THE TREATMENT OF THE COMMON COLD IN INFANTS AND CHILDREN*

ROGER L. J. KENNEDY, M.D.

Rochester, Minnesota

WHEN "the common cold" is mentioned before a group of physicians a clinical picture which is more or less similar is brought to the minds of the various listeners. That they will all entertain the same conception is, however, very unlikely. Certain physicians will visualize a process which involves only the nose: others, acute catarrh of the nasal and pharyngeal tissues. Still others will think of an inflammation of most of the upper part of the respiratory tract, including the nose, the accessory nasal sinuses, the pharynx, the larynx, the trachea, and the bronchi. In keeping with the effort which has been made in recent years to discard the term "cold," and to convey the meaning usually intended, the use of the term "infection of the upper part of the respiratory tract" is favored. It, therefore, seems wise to have the understanding that in infants and children, and perhaps in adults too, a cold may involve any or all of the component parts of the upper portion of the respiratory tract.

In consideration of the treatment of any disease the question of cause immediately arises. Logical therapeutic approach should consist of efforts to prevent entrance of the causative agent into the tissues of the organism, to increase the resistance of the organism to the attack of such agent or to destroy the agent if it has already invaded the tissues. At the present time, in spite of tremendous amounts of study and investigation, information regarding the agent or agents responsible for the common cold is relatively meager.

The belief that the common cold is due to bacteria such as the streptococcus, the pneumococcus, the bacillus of influenza, and the Micrococcus catarrhalis has changed to a belief that the etiologic agent is not a bacterium but a filtrable virus which may pass from one individual to another.[2] According to the newer ideas regarding the relation of bacteria to the common cold, however, the bacteria are not to be eliminated from the picture, but are to be regarded as secondary invaders and perhaps as playing the major etiologic rôle in the numerous complications of the common cold, which is produced by a virus.

Steps which may be taken to prevent the offending agent from reaching the organism are especially important in connection with young patients. It is generally agreed that infections of the upper part of the respiratory tract are serious in young individuals, and that the younger the child, the more frequent and dangerous are the complications. Although warnings have been issued regarding the contagiousness of colds, most lay people and indeed some physicians continue to disregard the rules of isolation which should be enforced in caring for any patient with a cold.

If thought is given to the meticulous care observed in isolating prematurely born infants from possible sources of infection and particularly from possible sources of infection of the upper part of the respiratory tract, the importance of isolation becomes evident. It is only too well appreciated that if a premature infant acquires a cold from exposure to an infected attendant, relative or family friend, the probabilities are very great that bronchopneumonia will follow and that the infant will die. If the patient is a mature infant or a young child, the chances that serious complications will develop are less but still are present.

---

*From the Section of Pediatrics, The Mayo Clinic, Rochester, Minnesota. Read before the annual meeting of the Minnesota State Medical Association, Duluth, Minnesota, July 1, 1938.

The intimacy of contact accounts for the spread of a cold from one member of a family to the others. The difficulty of enforcing isolation under the conditions that exist in most homes frequently discourages the physician as well as the family from efforts to isolate the affected individual or individuals. Nevertheless, the necessity and importance of protecting young children, and particularly infants, remains as a responsibility of both physician and parents.

Obviously, the child who has an acute cold does not belong in school. For the sake of proper care of the affected child as well as for the protection of the well pupils, the place for such a child is at home in bed, removed from other members of the family. In spite of this, teachers and school nurses encounter not only lack of coöoperation but even active opposition on the part of the parents of many children whom they properly exclude from school during the acute stage of colds. One of the duties of the physician is to instruct his clientele in the necessity of caring for these children in the way best suited to their prompt recovery and to the safety of other members of the family and community.

Opinion is divided in respect to the use of vaccines for the prevention of colds. Some feel that vaccines definitely reduce the frequency of colds. Others believe that although the incidence of colds may not be reduced, the duration of colds is decreased. It is the opinion of others that the chief benefit to be derived from the use of vaccines is in the decreased incidence of complications. There are those, too, who have not been convinced that cold vaccines are of any value.

If it is true that colds are due to filtrable viruses (and there is considerable evidence to support such a view), it does not appear logical that they can be prevented by vaccines made from streptococci, pneumococci or the bacillus of influenza. It is conceivable, however, that such vaccines may protect individuals against the attack of these bacteria if they are secondary invaders or if they augment the filtrable virus in its invasive effects.

It is rather well accepted that the bacterial flora of the nose and throat vary in different epidemics of colds and that autogenous vaccines, therefore, are preferable to stock mixed vaccines which may contain none of the prevalent organisms or may contain so few that they can have no antigenic effect. Since the subject is controversial and since protection afforded by vaccines is far from 100 per cent, their use should be advised only with reservations. It should be definitely understood that protection is not certain.[6] The same statement applies to the use of filtrable viruses for protection.[5] A report dated January, 1938, from the Committee on Immunization Procedures of the American Academy of Pediatrics is of especial importance in this connection. In the report it was stated that there is no method for producing passive immunity for the common cold and that no active immune principle of any proved value has been described.[4]

A good deal has been said and written regarding the rôle of vitamins in the prevention of colds. Of the numerous vitamins known to exist, vitamin A has received the greatest amount of attention in respect to prophylaxis of colds. Unfortunately, some facts which are highly essential to an evaluation of vitamin A are not known. Knowledge of the optimal amount of the vitamin necessary to the well-being of the individual and the criteria for determining insufficiency of vitamin A in the body have not been definitely established. The fact that vitamin A is found so abundantly in so many foods makes it appear unlikely that any considerable proportion of the population suffers from vitamin A want. In infants and young children, whose diets may be restricted, such a want may conceivably be present. On the other hand, the widespread use of cod liver oil, which is a rich source of vitamin A (1 teaspoonful contains 2,500 units, the adequate dose is about 5,000 units) insures a generous intake for many infants. Nevertheless, even infants who receive this presumably adequate amount continue to have colds.

The active treatment of the acute cold consists of measures directed toward symptomatic relief. Of these, the one single measure regarding which there is entire agreement is rest in bed. This is not difficult to enforce in the case of infants, but if the patient is a child of the runabout age or of school age, it is frequently very difficult to keep him in bed. This treatment should be continued during the acute stage of the infection, particularly if there is fever.

A great variety of sedatives have been used for their general effect as well as for their specific effect on the cough. Among those which have a general effect codeine has been employed a great deal. In addition to the general quieting effect, it tends to control any bothersome cough. The combination of codeine and papaverine may be administered to older children. The barbiturates are probably second only to codeine in extent of use in acute colds. If the patient is an infant ⅛ to ¼ grain (0.008 to 0.016 gm.) of phenobarbital may be sufficient to control restlessness, but larger doses may be employed. When pain is present as it is in cases of otitis media, codeine, sodium amytal, or nembutal usually afford relief and promote rest.

Antipyretic measures are indicated in some cases. If restlessness, sleeplessness and fever are present, a warm bath, preferably a tub bath, will lower the temperature a degree or two, which is usually sufficient to induce sleep. The antipyretic effect of the bath may be supplemented by drugs. For this purpose the salicylates, particularly acetylsalicylic acid, have been most widely employed.

Adequate humidity of the air in the patient's room is desirable and for that reason some means of introducing additional moisture may be necessary in homes which are not equipped with humidifiers. A steam kettle is perhaps the simplest means at hand for this purpose. Some comment may be made upon the use of steam kettles. No good purpose is served by the introduction of such excessive amounts of steam into the room that window panes run with water and condensation takes place on everything in the room, including the bedclothes and the patient's clothes. No special benefit has been demonstrated as a result of confining an infant or child in a tent into which pours a steady cloud of steam. Most of the steam kettles in use today are heated by unprotected electric elements and are therefore sources of danger from fire. Not only this danger attends the use of the steam kettle, but there must be kept in mind the possibility of the kettle being upset by another member of the family, or indeed by the patient himself, and thus causing burns.

The use of medicines such as eucalyptus or compound tincture of benzoin in the steam kettle does not add to the benefits derived from the use of the steam.

The diet need not be changed from that ordinarily taken. In infants a reduction in the amount of food, and replacement of the withheld food by water may be indicated during the first twenty-four to forty-eight hours. Such a step may prevent a gastric upset but the restriction usually need not be continued beyond the second or third day of the cold.

One of the most widespread practices in the treatment of colds must be mentioned chiefly for the purpose of condemning it. This is the indiscriminate instillation of "drops" and the spraying of various agents into the noses of infants and children. It has not been demonstrated that nasal drops or nasal sprays have any beneficial effects so far as the infection is concerned. The argument that they are used to relieve congestion and obstruction becomes very much weakened if consideration is given to the facts that they are not required for this purpose in most instances, that their effect is transitory and frequently followed by increased swelling and turgescence of the nasal mucous membrane and that they are liable to be toxic to the mucous membrane. In infants particularly, they have been held responsible in some cases for the initiation of otitis media by the washing of infected material into the eustachian tubes. Perhaps one justifiable use is in cases in which infants experience difficulty in nursing or taking the bottle because of nasal obstruction. In such cases not more than a drop of dilute 1:3,000 solution of epinephrine or a drop of 1 per cent solution of ephedrine may be placed in the nose before feedings.[1]

The practice of dropping oils of various kinds into the nose will probably lose considerable of its popularity as it becomes generally recognized that the oil may find its way to the lungs and there set up an inflammatory reaction, the so-called lipoid or oil pneumonia.[3]

Summary

The term "common cold" includes acute inflammations of any or all portions of the upper part of the respiratory tract. Treatment of the common cold may be preventive or symptomatic. The cause of the common cold may be a filtrable virus; bacteria may be coincident or secondary invaders. Isolation of infants and young children from infected individuals is of great importance. Vaccines may be given for protection with the understanding that, although they are not harmful, they may not be of benefit. Proof of the presence in food or vitamin preparations of any substance which specifically protects against colds is lacking.

Rest in bed, sedatives, humidity, baths, antipyretics and occasionally the use of epinephrine or ephedrine as nasal drops or a spray are the chief measures which may be used in symptomatic treatment.

Discussion

Dr. Andrew Sinamark, Hibbing: This paper is an excellent exposition of the present day trends on the subject of the common cold. I agree with Dr. Kennedy's opinion that these cases are often over-treated. I believe that this is especially true as far as aqueous solutions in the nose are concerned. Nasal mucous membranes often show the effect of over-treatment with douches and sprays. An aqueous solution in an ordinary atomizer can set up small hemorrhages of the membrane.

In spite of the recent tendency to do away with oils in the nose, I still believe that oils are valuable. In spite of the fact that they have been shown to be dangerous in the case of infants, I do not feel that this is true in older children. The instillation of a nasal oil containing no more than 1 per cent menthol, an equal amount of camphor and the addition of other aromatics to make the mixture more agreeable, certainly gives the patient the sensation of better ventilation of the nasal passages. Furthermore, I believe that it actually does cause a little shrinkage. If the mixture contains a small amount of iodine (about 0.1 per cent) it causes a mild hypersecretion of the membranes which results in a depletion, which I believe is of more prolonged effect than instillation of epinephrine or ephedrine. Furthermore, there is no danger of oils initiating otitis media by washing infected material into the eustachian tubes.

EXPOSURE OF THE BODY TO UNEQUAL TEMPERATURE

A Factor in Pneumonia

CHARLES W. MORE, M.D.

Eveleth, Minnesota

In the early years of my professional life at Ely, Minnesota, I came in contact with a great many typhoid fever patients, cared for in ordinary dwelling houses, boarding houses, and shacks, heated by stoves.

It was noticed during the late fall and early winter that those patients with typhoid fever, having complications, as bronchitis or pneumonia, were occupying beds close to a window, which was the usual situation in the crowded boarding houses, the side of the bed being close to the window and the top of the bed being on a level with the bottom of the window. The heating stoves were in the room or in an adjoining hall, near the door of the room. The windows were usually closed and protected by storm windows, but the radiation from the glass produced a temperature lower on that side of the body next to it than on the side of the body toward the warm room.

The frequency with which pneumonia occurred in typhoid fever patients when thus exposed was so apparent that I had no difficulty in teaching my people its dangers, and obtaining the coöperation of the patient and his family and friends to correct the situation, which resulted in a noticeable reduction in lung complications in this disease (typhoid fever). And consequently the first question asked by the patient when I called to see him thereafter would be, "Doctor, is my bed in the right place?"

Carrying the observations further, after moving to Eveleth, it was noticed that many babies having pneumonia were those occupying a crib or baby carriage near a heating stove. On one side of the patient would be the stove and on the other a large window, or an open archway into an unheated parlor or a cold bedroom, thus exposing the patient to unequal temperature.

In a number of instances I correctly predicted that children and babies so exposed would have pneumonia. In one instance a newborn baby was left in its receptacle between a heating stove and an open archway into an unheated parlor. The parents were warned of the danger, but did not heed it. The baby died of pneumonia during the winter. When they later built another house, they sought my advice as to the proper placing of the windows and doors so that they would have ample space for the beds.

In another instance, a family having two children, aged five and eight years, moved into an apartment house. While attending the sick mother of the children, I noticed the bed for the children was next to a window, the bottom of the window being on a level with the top of the bed. The window was protected with a storm window but covered with frost. The room contained a small heating stove opposite the children's bed. The parents were informed in no uncertain terms of the danger and told positively that the children would have pneumonia if this condition were allowed to continue. The advice was not heeded and in six weeks both children had pneumonia. One died.

So emphatically was it impressed upon me that unequal temperature is an etiological factor in pneumonia that, when building my own small hospital years ago, I had the windows and doors to the rooms and wards placed opposite each other, leaving ample wall space for beds without exposing the patients to unequal temperature. Pneumonia has never developed in typhoid fever patients entering the hospital early and free from lung complications.

At one time during an epidemic of typhoid fever, the hospital ward was overcrowded and a patient, occupying a bed next to a wall twenty-two feet from a double window, was observed to be coughing. While examining the patient, I distinctly felt a draft of air on the back of my head and neck as I leaned over the patient to examine the side of his chest which was next to the wall. There was a stiff breeze coming through the top of the windows twenty-two feet away and was directed toward the ceiling by a contrivance at the top. The wind followed the ceiling and continued down the wall where the patient was. His position was, of course, immediately changed and he promptly recovered.

I have a patient who, if he leaves a warm room and walks outside while a cool breeze is blowing, will sneeze, and his nose will begin to discharge. But if he will turn around so that all parts of his chest are cooled equally, this condition soon stops.

I have observed frequently, and many practicing in the country have undoubtedly noticed the same thing, that while making what I considered to be the last call on a patient with tonsillitis, I would find the patient downstairs on a lounge next to the outside wall or window, not far from the heating stove. To the question, "How are you feeling?" the reply was, "I was feeling much better and thought I would come downstairs, but (making an effort to swallow) I don't feel as good as I did." This is another example of exposure to unequal temperature at an inopportune time, when the patient was not in a condition to stand it. Some people are more susceptible to this unequal temperature than others.

Dr. Preble says that in certain dwelling houses there seems to be a predisposition to pneumonia. It would be interesting to know the relationship of the beds to the windows and heating unit.

It is in those cases of pneumonia in children, where the parents can not or will not protect the patient from unequal temperature, that I found the pneumonia jacket, frequently changed, most useful, chiefly, I believe, on account of its maintaining equal temperature.

It will be noticed that those advocating cold fresh air for children with pneumonia, have placed them in cold rooms. Here the patient gets the benefit of the fresh air without exposure to unequal temperature.

In conclusion, I regard exposure of the body to unequal temperature to be a predisposing etiological factor in pneumonia, as well as the cause of so-called "colds in the head," coryza, tonsillitis, pharyngitis, et cetera.

AUTOGENOUS STREPTOCOCCUS VACCINES IN THE TREATMENT OF ALLERGIC CONDITIONS, WITH SPECIAL REFERENCE TO THEIR USE IN BRONCHIAL ASTHMA*

Report of Cases

R. S. YLVISAKER, M.D.

Minneapolis, Minnesota

BEFORE entering into the discussion of the subject chosen for this presentation, it would probably be well to survey briefly the field of allergy as a whole. This is done in order that the phase of the subject under consideration may be viewed in its proper perspective.

One is impressed, first of all, with the fact that the great majority of allergic cases present a family history of some form of allergy. This is becoming more and more apparent as the field has come to embrace conditions previously not considered in this light. To the old triad of asthma, hay fever, and eczema, must now be added the other forms of allergic rhinitis, sinusitis, and conjunctivitis, nasal polyps, many of the recurring wet colds, some cases of recurrent bronchitis, many cases of migraine, a large number of the vague gastrointestinal dyspepsias, possibly peptic ulcer, urticaria and the angioneurotic edemas, the spasmophilic conditions of childhood and, lastly, but assuming more and more of a prominent position, some of the chronic infectious diseases, chiefly tuberculosis and the rheumatic group. Probably other conditions should be included.

One is impressed also with the frequent association of these conditions with certain disorders of metabolism, endocrine disturbances, mineral imbalances, particularly of the calcium-phosphorus group, and with the fact that these conditions are frequently precipitated or aggravated by emotional upsets and by dietary indiscretions and deficiencies.

We are confronted, therefore, with a group of conditions which have as their point of origin a fundamentally deranged constitutional background. The distressing thing is that, in spite of the large amount of work which has been done in the field of immunity and in tissue reactions to foreign substances, very little is known regarding the real biological and physico-chemical factors involved. The present-day methods of diagnosing and treating these conditions by means of skin testing, leukopenic indices, elimination diets and the injection of various specific or non-specific proteins are all aimed at merely certain symptoms or manifestations of the fundamental constitutional disorder. In the present state of our knowledge, rather than to limit ourselves to these few procedures, it is more important that we approach these cases from every possible angle. The family history, including the health of the children, if any, must be carefully scrutinized for the particular type of background involved. The personal history should be thoroughly investigated not only for previous histories of the more obvious types of allergic manifestations but more particularly for evidence of susceptibility to acute and chronic infections, dietary idiosyncrasies and emotional conflicts. To the general physical examination and the usual blood and urine studies must be added complete examination of the stools, investigation into possible metabolic disorders, mineral imbalances especially of the calcium-phosphorus group, and endocrine disorders, as well as a complete study of the skin reactions to the various allergens.

Therapy should then be instituted for each and all of the abnormalities discovered. A word of warning should be inserted here. The error of removing too many articles of food from the diet is made more frequently than removing too few. The use of too severe elimination diets frequently leads to dietary deficiencies which in the end aggravate rather than ameliorate the patient's symptoms. It should constantly be kept in mind that all the essential food elements must be included in the diet even though it be necessary at times to do this at the expense of retaining foods to which the patient is sensitive.

---

*Read in part before the Minnesota Society of Internal Medicine at its meeting held in October, 1937, Saint Paul, Minnesota.

We come then to our discussion of the use of vaccines. It is hoped that the introductory remarks have indicated that the use made of vaccines in allergy by the writer forms but one small link in the treatment of this large group of disorders. It is admitted from the outset that this study is purely a clinical one and that the series presented is too small to provide the basis for any definite conclusions. If this study will, in some small measure, add to the mass of evidence presented by others or possibly provide a new point of view for further study in certain directions, its aim will have been accomplished.

The first report of the use of vaccines in asthma which could be found in reviewing the literature, was that by Carmalt-Jones[3] in 1909. He isolated a Gram-negative bacillus from the sputum of an asthmatic, made up a vaccine and administered it subcutaneously, starting with a dose of twenty-five million organisms. A marked improvement resulted in this case. He then used the same vaccine in seventy other cases, fifty-two of which he reports. Good results were obtained in thirty-nine. The same year G. W. Davis[5] reported marked relief in a case of acute, generalized eczema following the use of a staphylococcus vaccine. In 1911 John T. Farrell[6] reported the use of autogenous vaccines in three cases of chronic, long-standing, severe, generalized eczemas, with recovery in each case. In the first case a staphylococcus albus was recovered from weeping portions of the skin; in the second a mixed culture, chiefly a large diplococcus, from a skin papule; and in the third, a colon bacillus from a grossly infected urine. Wood[19] in 1915, after having previously used staphylococcus vaccines in several cases of pustular eczema, tried autogenous streptococcus vaccines obtained from foci in the mouth, nose and throat, with good results in four cases.

From this time on, reports become more and more numerous so that only a few can be mentioned here. Chiefly some of those dealing with the use of vaccines in bronchial asthma will be reported. In 1917, Sicard[14] reported the use of autogenous streptococcus (hemolyticus and viridans) vaccines obtained from sputum cultures. He gave the vaccine subcutaneously and felt that a local reaction was necessary in order to obtain good results. Hutcheson and Budd[9] used a mixed vaccine containing usually streptococcus, staphylococcus and micrococcus catarrhalis, together with a small amount of the broth filtrate. They considered the good results to be due to the presence of an anaphylatoxin produced in vitro by the bacteria and called attention to the possibility of anaphylactic shock if the interval between injections was allowed to go over eight to ten days. Rogers,[12] in 1921, reported forty cases in which he used autogenous streptococcus vaccines, obtained from sputum cultures, subcutaneously, with only 15 per cent failures. G. Tyler Brown[2] differentiated between bacterial or non-sensitive asthma and protein-sensitive asthma. He cultured the sputum and isolated each organism present, made a vaccine from each and tested the skin intradermally with each organism, used the twenty-four hour reaction as a guide, and used only those in treatment which reacted positively. He, too, felt that a local reaction was necessary in order to obtain results. All but 10 per cent of his 144 cases were relieved or cured. Rackemann[10,11] in various articles concluded that just as good results were obtained with stock vaccines as with the autogenous, but insisted that relief from asthma came only with and was proportional to the local reaction following subcutaneous injection. Thomas and Touart[15] cultured the sputum and all possible foci, made a separate suspension of each organism isolated, and used those which gave a positive intradermal twenty-four hour reaction. They continued the injections for several weeks after relief was obtained. They also reported a case sensitive to all kinds of feathers which showed no improvement when the feathers were removed from the environment. The administration of vaccine resulted in marked improvement, which became complete when the feather pillows were again removed. Later on, the use of the pillows was not followed by recurrence.

Feinberg[7] states that in the majority of cases bacterial vaccines act in a non-specific manner, but Vaughan[17] denies this and calls attention to evidence pointing conclusively to the occurrence of a specific bacterial allergy in many cases, although he agrees that the best results from vaccines are obtained when a local reaction occurs. He uses vaccines for two purposes, namely, to desensitize and to immunize. For the former, small doses must be used; and for the latter, large doses. Voorsanger and Firestone[18] do not believe in a specific action of vaccines. They call attention to the frequent beneficial effect of stock vaccines in cases of asthma in which the onset could not be traced to an infectious process.

Bray,[1] in his book entitled "Recent Advances in Allergy," reviews in some detail the role played by bacteria in asthma. He calls attention to the work of Wilmer and Cobe (1933), who compared the incidence of bacteria in the sputa of five hundred asthmatics and two hundred controls. In asthmatics, the highest incidence was that of various types of streptococci, 67.4 per cent of all cases; while in the controls the highest incidence was shown by staphylococci (albus and aureus), 84 per cent of all cases. They further state that similar results are obtained in treatment with stock and autogenous vaccines unless only those autogenous vaccines are used which give a positive skin reaction. The latter give the best results. However, he also cites the work of Knott and his co-workers, who claimed that, in eighty-five cases out of one hundred thirty-two, the sputum was eosinophilic. Forty-two of the eighty-five showed Gram-negative bacilli in the plugs of bronchial secretion. In the remaining forty-seven cases, the sputum did not contain eosinophiles and only six of these showed Gram-negative bacilli in the plugs. Calling attention to the work of Harkavy (1929), who found a spasm-producing substance in the sputum of asthmatics during paroxysms, which was absent during the free interval, Knott and Oriel (1930) suggested the possible origin of these histamine-like substances from the Gram-negative bacilli, since culture extracts from these organisms have been known to give effects similar to those obtained from the sputum itself. Knott concluded, however, that Gram-negative bacteria can produce clinical asthma only in those people whose bronchi are already in such a state that slight further stimulation will produce bronchospasm. Acton and Dharmendra (1933) failed to confirm the histamine-like effects produced by cultures of the Gram-negative bacilli.

Many recent reports have been made of the use of vaccines in the treatment of asthma. Among these is that of Rozendaal and Maytum[13] in the United States, who used both autogenous and stock vaccines with similar results from each and concluded that the effect produced was non-specific. Vallery-Radot, Blamoutier and Nitti,[16] in France, found that the hemolytic and viridans types of streptococcus were predominating organisms in the sputum of patients suffering from asthma, as well as those having chronic bronchitis. They believe that bacterial vaccines act only in those cases with bronchitis and that the improvement in the asthma is secondary to the improvement in the bronchitis. Harley,[8] in England, subdivides asthma into four types: (1) those hypersensitive to non-bacterial substances; (2) the same plus secondary infections or toxemias; (3) bacterial asthma; (4) the same plus secondary non-bacterial sensitizations. He states that vaccine therapy is indicated in types 2, 3, and 4.

Our interest in the use of autogenous vaccines began about ten years ago in the treatment of chronic arthritis. As the allergic manifestations of this group of disorders came more and more to the foreground and as common knowledge indicated that many of the allergic group of conditions, chiefly bronchial asthma, had their onset during or following acute infectious episodes, we gradually extended our use of autogenous vaccines to include this latter group. As most of the reports which appeared incriminated the various types of streptococci as the predominant organisms in both groups, our efforts have come to be directed toward their isolation and use in autogenous vaccines. To begin with, they were used subcutaneously exclusively. Although good results were obtained, progress was often slow and indefinite. When Clawson,[4] of the University of Minnesota, reported his work on the intravenous administration of streptococcus vaccines in chronic arthritis, we gradually adopted the method in our work.

In the series of cases about to be reported, cultures were made from the sputum and any possible focus or foci of infection, including the nasal mucosa, the washings from sinus irrigations, the pharynx, the tonsils (preferably after removal), pyorrhea pockets, roots of extracted teeth showing apical abscesses, the cervix uteri, stools and directly from the rectal mucosa through the proctoscope. Plain dextrose broth and dextrose brain broth were the only media used except in an occasional case in which difficulty was experienced in obtaining the strep-

tococcus in pure culture. In such cases the mixed culture was plated out on blood agar and the pure culture obtained by subculturing individual colonies. The media had previously been titrated to a pH of 7.6. It was considered extremely important that culture media be at incubation temperature at the time the culture was taken and then transferred immediately to the incubator. It was felt that in this way pathogenic streptococci could be more easily isolated.

The bacterial sediment was separated from the supernatant broth and washed three times with normal saline. The organisms were then suspended in normal saline, subjected to heat at 60° C. for ninety minutes and the suspension tested for sterility before being used. Two drops of a 4 per cent phenol solution were added to 10 c.c. of the suspension as a preservative. A bacterial count was made in order to standardize the vaccine. This suspension was then used as a stock vaccine from which dilutions were made for administration. The undiluted vaccine was used in making skin tests, the intradermal method being used. In performing the skin test, just sufficient material to form a small bleb (usually about 0.01 cc.) was injected. If streptococci were isolated from more than one focus, skin tests were made of each, and only those used which gave positive reactions.

The initial dose of the vaccine varied from twenty-five thousand to one hundred thousand organisms. (Protein determinations have been done on a few of the vaccines. The results of these indicate that this dose contains approximately 0.00001 to 0.00004 mgm. protein.) To begin with, injections were given every three to five days. As improvement became established, the interval was lengthened to five to seven days. The interval was never allowed to go over seven days without drastically reducing the dose. The size of the dose was gradually increased until definite improvement was noted. No further increase was made as long as improvement or relief of symptoms was maintained. Any reaction following a dose called for a marked reduction in the next dose to one-fourth or one-tenth of the preceding dose. If possible, the injections were continued over a period of at least six months so as to prevent recurrences. In several cases they have been continued for periods of two to three years, with occasional rest periods of six to eight weeks.

The methods used in this study differ, then, in three main particulars from those used by others: (1) the vaccine is given intravenously in the majority of cases; (2) extremely small doses are used and a great deal of caution exercised in determining the size of each succeeding dose; and (3) long periods of continuous desensitization are employed for the purpose of preventing relapses.

Table I shows the total number of cases treated, the distribution according to diagnosis, the number treated intravenously and subcutaneously respectively, and the results of treatment. It will be noted that fourteen of the twenty-three cases were cases of bronchial asthma. In the miscellaneous group, the cases of recurrent sinusitis, chronic conjunctivitis and chronic iritis were included because they presented definite evidence of sensitization to bacterial proteins. The vaccine was administered intravenously in fifteen cases, subcutaneously in eight cases. In reviewing the results of treatment, it is seen that seventeen of the twenty-three cases obtained complete relief or nearly so. There were three failures, all cases of bronchial asthma. Further reference to these results will be made later.

In Table II the number of cases giving a history of onset associated with or following an acute infectious process is shown. These cases are designated, for convenience, the infectious cases. Eighteen of the twenty-three cases had such an onset. This Table also indicates the number of cases with a personal history of other manifestations of allergy and those with a family history of allergy. These figures were obtained from routine histories. It is felt that the number of positive histories would very likely have been increased if more detailed histories had been obtained. It shows, however, a similar distribution of positive histories in the infectious group as in the entire series. This Table also shows the number of cases with positive intradermal tests to proteins other than bacterial. These were carried out in eighteen cases of the series. Each case was tested with a large number of substances, especially foods. All cases gave a certain number of positive reactions. A subdivision was, therefore, arbitrarily made into those with few reactions (less than ten), and those with many. Again, a similar distribution is seen in the infectious cases as in the entire series. This Table finally reveals that sixteen of the eighteen cases tested intradermally with their own vaccine showed an immediate positive reaction of the protein sensitization type.

The result of studies shown in Table II is in direct contradiction to the statements made in many of the previous reports, namely, that the bacterial or infectious types of cases belong to a separate insensitive group in which family histories of allergy and positive skin reactions of the immediate protein sensitization type are rare.

TABLE II

	Asthma	Misc.	Total
Total cases	14	9	23
Infectious cases	12	6	18
Personal history of other manifestations of allergy:			
Total	7	5	12
Infectious	6	3	9
Family history of allergy:			
Total	6	3	9
Infectious	6	2	8
Cases with positive skin reactions to other proteins:			
Total—few	4	0	4
many	8	6	14
Infectious—few	3	0	3
many	6	4	10
Skin reaction to vaccine:			
Total number done	11	7	18
Immediate reaction	10	6	16

Very little difference in the end-results was noted between those given vaccine subcutaneously and those given it intravenously. The definite clinical impression was gained, however, that more prompt and precise improvement was obtained in most of the cases receiving the vaccine intravenously.

In two cases in which the administration of the vaccine was begun intravenously, it became necessary later to change to the subcutaneous route of administration because of severe reactions. In one of these, the reactions appeared soon after treatment was started even though minute doses were given. Soon after the subcutaneous method was begun, a slow but steady improvement resulted which finally led to complete relief. In the other case, intravenous administration was originally followed by prompt and almost complete relief of symptoms. This continued for about two months, when reactions to each dose began to appear until almost constant asthma was again present in spite of drastic reduction of dosage. The subcutaneous method was then substituted and recently gradual improvement has again definitely become apparent.

Two of the three failures can possibly be explained on the basis of incomplete management. In one case, after showing considerable improvement, the patient discontinued taking the vaccine. After a few weeks he developed a severe recurrence and died suddenly during a period of almost constant asthma. Examination previously had shown evidence of myocardial disease, but it was definitely felt that he was suffering from a true bronchial asthma rather than a cardiac asthma. The second case was that of a man, 44 years old, somewhat below par in intelligence. He had had asthma for fifteen years, the onset following an acute respiratory infection. He was sensitive to many foods and pollens, in addition to bacteria. It was almost impossible to obtain proper coöperation in carrying out his dietary management and this, no doubt, accounted at least partially for our failure. Another case of severe asthma, not included in this series because of insufficient treatment, had been given four or five intravenous doses of an autogenous vaccine at 5-day intervals. The administration of the next dose was then unavoidably delayed until the 8th day. Although the dose was the same as that previously given, it was followed by a severe exacerbation of her asthma within a few hours. Further treatment was refused.

Good results in this series can be illustrated by the following cases.

A girl, aged fourteen, had developed a severe asthma following a bronchopneumonia four years previously. Her mother and one aunt had had asthma and there was hay fever in her father's family. She had suffered previously from frequent head colds. Before coming to us, she had been studied carefully by another physician. She had been found sensitive to many foods by skin tests, but dietary management on this basis had produced no results. We felt that eliminating all the foods to which she was sensitive involved the danger of dietary deficiency, so she was placed on a well-balanced diet with high vitamin content and limited in carbohydrates, without regard to the skin tests. She was given calcium salts by mouth. This management produced very little change in her asthma, but, almost immediately after small doses of vaccine were started intravenously, a marked improvement occurred. This has been maintained for a year and she has been able to return to school.

Good results have not been confined to those cases with a history of onset following acute infections.

A physician, aged thirty-one, first came to Minnesota in January, 1936. He had previously never had seasonal hay fever although he had been subject to frequent head colds. In August, 1936, he was taken with a typical severe hay fever which persisted through the ragweed season. Instead of being relieved when frost came, however, the severe allergic type of rhinitis persisted through the fall and winter. He was found to be markedly skin-sensitive to many foods and pollens, including ragweed. A streptococcus was isolated from his nasal secretions. The intravenous administration of this vaccine was promptly followed by marked relief of his symptoms. This year he has been successfully carried through the ragweed season on a combination of his vaccine intravenously and pollen extracts subcutaneously.

In conclusion, then, we would like to suggest the following points for further study:

1. The so-called bacterial or infectious types of allergy, especially asthma, are fundamentally similar to other forms of allergy.
2. The beneficial effect produced by minute doses, both subcutaneously and intravenously, are probably due, not to a foreign protein shock therapy, but rather to a specific type of desensitization.
3. The intravenous route of administration produces more prompt and precise results than the subcutaneous. Severe reactions may be expected following intravenous administration if too large doses are used or too long an interval is allowed to elapse between doses.
4. The beneficial effects of vaccines in allergic states, especially asthma, are not confined to the primary bacterial allergies but may also be of value in certain cases in which the bacterial allergy is secondary.

ACUTE MASTOIDITIS*

J. G. PARSONS, M.D.

Crookston, Minnesota

In treating the subject which has been assigned to me, it is obvious that only the high spots can be touched within the limits of the time which is available. I have therefore thought best to emphasize some of the most important points, as they concern the general practitioner, and make some comment on certain faulty conceptions which are quite commonly observed by otologists.

The most commonly met picture of acute mastoiditis is that of a post-aural pain, tenderness and swelling following a discharge from the ear which has continued for some time and has lessened prior to the occurrence of these symptoms. These symptoms indicate an involvement of the mastoid cells, with more or less bony necrosis, and are supposed to be due to an extension of middle ear suppuration because of pressure resulting from poor drainage from an opening in the drum head.

The chief considerations are the relief of pain and the prevention of intracranial complications which may occur as the result of extension of the infection inward instead of outward. Surgical treatment consists in opening the mastoid bone, curetting out softened bone and keeping the wound open by gauze dressings until it has healed by granulation—a process requiring a varying length of time, and usually evidenced by a good sized depressed scar and quite probably serious damage to hearing.

Adhering too closely to this general idea of acute mastoiditis often results in some fallacious reasoning as to pathology, diagnosis and treatment.

While the most common avenue of infection of the middle ear is through the eustachian tube, by continuity of tissue from an infected naso-pharynx, the infection being forced through a patent tube by blowing the nose, coughing, sneezing and vomiting, it should be borne in mind that this infection may be carried through blood and lymph channels.

The type of infection is a matter of considerable importance. Frequent studies of smears from a discharging ear give important information as to the pathological probabilities which are present. Streptococci, especially the mucosus capsulatus, are liable to be very destructive to bone. Predominance of staphylococci points to a long drawn out infection.

Infection of the middle ear practically always means a coincident infection of the mastoid antrum, where germs of a more virulent type, especially if there is not free drainage, find an easy entrance to adjacent mastoid cells. There is a certain analogy between the bony cavities of the temporal bone which are connected with the mucosa of the naso-pharynx and those of the nasal accessory sinuses. Most acute infections of the sinuses clear up spontaneously if there is good drainage. So also do infections of the middle ear, many of which drain through the eustachian tube. If the eustachian tube is swollen and does not permit free drainage it is the pressure on the drum as well as the inflamed mucosa which causes pain, especially in the presence of a virulent infection.

It is highly probable that most cases of acute mastoiditis were coexistent with a middle ear infection from the start, and that many of them clear up if given a chance to drain adequately. Adequate drainage of the middle ear when there is a bulging drum head or if there has been a spontaneous rupture with pus in the external meatus must be borne in mind as an essential in heading off mastoiditis. I use the words

---

*Read before the annual meeting of the Minnesota State Medical Association, Duluth, Minnesota, June 29, 1938.

"heading off" advisedly, for it implies not only the prevention of mastoid infection, but the checking of a beginning infection as well.

One of the fallacies too frequently met is the notion that as long as an ear is draining there is no cause for concern. It is essential to actually see the drum head and note the size of the perforation. If it is not freely open it should be enlarged, repeatedly if need be, to provide a safety valve of adequate drainage.

If there is post-aural pain, even if there is no discharge, the mastoid should be carefully investigated, for there is sometimes involvement of the mastoid without aural discharge. Pressure over the antrum opening of the mastoid emissary vein or over the mastoid tip will be painful in most cases although if the bony cortex is very thick this tenderness may be slight.

Edema will be noted in many instances when the cortex of the mastoid process is thin, as in infants, but does not necessarily indicate the need for operation. However, a distinct post-aural swelling, especially if the ear is displaced, is very suggestive of mastoiditis. Care should be taken to exclude a boil in the external canal which may produce both edema and tenderness similar to mastoiditis. If the tenderness is more marked when pressure is directed toward the external meatus instead of away from it, furunculosis should be suspected. A swelling of the posterior superior wall of the external canal adjacent to the drum head is significant of involvement of the mastoid antrum, which lies immediately within.

The presence of post-aural pain, tenderness and swelling of the external canal, often called the "dip," usually a diagnosis of probable mastoiditis. Temperature and pulse changes give further information, but there may be a well developed mastoiditis without much disturbance of temperature or pulse. A steady high temperature suggests a blood infection or meningitis, while a sudden high temperature, followed by a drop and chill, point toward thrombosis of the lateral sinus, which lies in immediate relation with the cells of the mastoid.

The blood picture is of value as in infections elsewhere. Persistence of a high polymorphonuclear percentage is an indication for operation.

Swelling below the mastoid tip is sometimes mistaken for a neck abscess not associated with ear infection. This is not infrequently due to an extension of infection from one of the larger mastoid cells found in the tip, the so called Bezold's mastoiditis. Likewise the cells which are found in the root of the zygoma may be involved and swelling there may throw one off the track of diagnosis if he is looking for all the classical symptoms, including post-aural swelling.

It is well to observe here that infection of the mastoid bone may jump across a sound area, through vascular channels, and be overlooked at the time of operation, unless one makes it a point to make a complete exenteration of the mastoid cells, a standard procedure in operating. Any discharging ear is dangerous. Heath of London used to refer to the mastoid as "the aural appendix." It is wise to have the same respect for this appendix as for the one found in the abdominal cavity.

An ear which has been discharging for more than a week without diminution should be held under suspicion. The drainage must be kept free, and the character of the infection watched, especially if streptococci are found. Prolonged discharge points to involvement of an area larger than the tympanum. It means also damage to hearing in proportion to the duration of the discharge. While one may not be arbitrary about the matter, it is a wise rule to conclude that a persistent ear discharge lasting three weeks means mastoid infection, and quite probably the need for operation.

It is true that Nature is wonderful but I believe it is wiser to err on the side of early operation, save a few more lives and many more hearing ears, than to be too conservative, which attitude is popular at present.

It is true that a reasonable delay in operating allows time for walling off of the infected area, but this calls for the exercise of sound surgical judgment, which with the experienced otologist becomes almost intuitive. It is also true that properly taken and properly interpreted x-ray films are valuable, but can not replace accurate clinical observation.

Time will not permit more than a passing reference to mastoidectomy, and post-operative care. However, it should be emphasized that mastoid surgery calls for a degree of technical skill, not only in determining when but how to operate on an individual case. The post-operative care is also important.

For many years I have used the blood clot method, and have seen about 60 per cent of my cases heal with primary union, with less damage to hearing and with much better cosmetic results than is obtained by open methods. The method calls for care in completely removing all infected and devitalized tissue, the avoidance of antiseptics in the wound, careful asepsis, and subcutaneous closure, preferably with copper wire.

Post-operative care calls for frequent change of ear drains, making sure there is a free incision of the drum head at operation. The procedure amounts to practically converting a mastoiditis into a simple otitis media. If the wound should break down it is a simple matter to spread the lower angle enough to insert a strip of rubber tissue, which I have found to be all the drainage required in any mastoid wound. The use of gauze packs is painful to the patient and damaging to regenerating tissue. The wire sutures are easily removed with a single pull in about a week. A collodion cocoon in cases which have a slight oozing is fully as satisfactory, and much less unsightly than a head bandage.

The question sometimes arises as to the advisability of sending patients home for post-operative dressings. I believe this is inadvisable, for the technic of making mastoid dressings calls for almost as much skill and judgment as operation. Further it is important to observe the progress of the middle ear closely in order that the return of normal function may be given every chance.

It should be borne in mind as stated before that we are concerned not only with saving life but with the conservation of hearing.

Discussion

Dr. Walter E. Camp, *Minneapolis:* The usual features of acute mastoiditis are well understood by both general practitioners and otologists. Dr. Parsons has very forcibly emphasized some of the unusual features in both surgical and non-surgical mastoiditis. The diagnosis of surgical mastoiditis in most cases is not difficult; not infrequently, however, cases are encountered which are very misleading.

In all cases of acute suppurative otitis media the mucosa of the mastoid antrum and mastoid cells is involved to a variable degree. The amount of involvement of the mastoid, the severity of symptoms, the question of surgical intervention, and liability or frequency of serious complications are features which are determined by such factors as: (1) type and virulency of the invading organism; (2) speed and adequacy of drainage of the middle ear; (3) the anatomical type of mastoid involved; (4) immunilogical and therapeutic response of the individual affected.

In some cases, acute mastoiditis, even with some bony cell destruction, will heal without surgical interference. This occurs most often in cases where the invading organisms are not exceedingly virulent and the cells surrounding the mastoid antrum are large enough not to be blocked by edema and granulations.

Early and adequate drainage of the middle ear as emphasized by Dr. Parsons is exceedingly important to prevent surgical mastoiditis. Acute mastoiditis, due to hemolytic streptococcus, will, in some cases, respond early to sulphanilamide.

In this usual routine of office and clinical work one should always be alert for the unusual or atypical type of mastoiditis with a minimum of clinical symptoms and signs. During the past five years it has been my privilege to see five of these unusual cases. Three of them were cases of frank otitis media in which early and adequate drainage was secured. The patients were symptom-free except for pain and slight aural drainage. There was no fever, no tenderness of the mastoid, no prolapse of the posterior canal-wall, no leukocytosis. Roentgenograms in these cases showed only slight cell destruction. All three cases developed meningitis, two from direct extension through the petrous pyramid and one through vascular channels. The other two cases were of the so-called latent or "silent" mastoiditis. The ear drums were normal. There was no perforation or history of aural discharge. Both these patients developed lateral sinus thrombosis and bacteremia, and both survived following the required operation.

These unusual cases should keep one always alert and should emphasize the clinical importance of routine and, if necessary, repeated x-rays. They should also emphasize the clinical importance of one very urgent symptom—namely, pain. Persistent mastoid pain or headache, even in the absence of any other clinical sign, except possibly positive x-ray, should be sufficient evidence to justify exploration of a questionable mastoid.

The optimum time for surgery in acute mastoiditis is after a variable amount of necrosis has developed and opportunity given for the development of some degree of local tissue immunity—an interval of from ten to fifteen days in the usual case. In some severe infections, however, especially those complicating scarlet fever and pneumonia, a "malignant" type of mastoiditis can develop within four or five days and demand early operation.

THE PROBLEM OF GASTRODUODENAL HEMORRHAGE*

ALBERT M. SNELL, M.D.

Rochester, Minnesota

ALTHOUGH it is true that bleeding from peptic ulcer may occur without serious consequences in many instances, there are few more urgent clinical situations than those presented by massive gastroduodenal hemorrhage and few that on occasion may make such heavy demands on the courage, judgment, and decision of the physician. The problems of diagnosis and prognosis hinge upon a decision as to the source of bleeding, the type of vessel involved and the rate at which blood is being lost; the problems pertaining to treatment are concerned with meeting the immediate emergency caused by the hemorrhage, the prevention of further bleeding, and later, the matter of dealing with the hemorrhagic lesion itself. The present discussion will be concerned chiefly with brief considerations of the foregoing points with special reference to current views on the problems of treatment.

Statistical Considerations of the Sources of Hemorrhage

The sources of bleeding, as determined from a series of 688 consecutive cases of hematemesis taken from the files of The Mayo Clinic, have been recently tabulated by Rivers and Wilbur.[31] It was found that in about 90 per cent of cases the bleeding came from demonstrable intrinsic lesions in the stomach or duodenum; that in about 5 per cent of cases diseases of the liver or spleen were responsible, hemorrhage ensuing from ruptured esophageal varices; and that in the remaining 5 per cent of cases the source of bleeding was ascribed either to miscellaneous or unverified causes. This miscellaneous group included rare instances of bleeding due to such uncommon causes as blood dyscrasias and hemorrhagic cholecystitis; in this group it was not possible to exclude erosive lesions of the gastroduodenal mucosa.

Since most of the hepatosplenic lesions present a fairly definite clinical picture and constitute an entirely different problem in treatment, the discussion to follow is concerned only with the 95 per cent of cases in which lesions of the stomach or duodenum were known to be present or in which the source of the blood lost was not definitely demonstrable.

By far the commonest cause for diffuse gastro-intestinal bleeding in the 90 per cent of cases in which it is due to an intrinsic gastroduodenal lesion appears to be duodenal ulcer; it accounted for the bleeding in 57 per cent of the cases in the series just mentioned. Secondary anastomotic or recurrent peptic ulcer was the source of hemorrhage in 14 per cent of the cases, and gastric carcinoma ranked third, making up 12 per cent of the group. Gastric ulcer was responsible for hemorrhage in 6 per cent of cases. Miscellaneous lesions of the stomach, including benign tumors and polyps, were the least common cause, comprising only 1 per cent of the total. Allen's figures on the causes of massive gastroduodenal hemorrhage in 231 cases showed a somewhat different distribution of lesions, the incidence being as follows: duodenal ulcer 41 per cent, carcinoma 20 per cent, gastric ulcer 18 per cent, gastrojejunal ulcer 3 per cent, and miscellaneous or unverified lesions 2 per cent; in the remaining 16 per cent of cases the bleeding came from esophageal varices. Since gastric cancer usually produces cachexia before severe bleeding occurs and since benign tumors are decidedly rare, these causes may be further eliminated from discussion at this point and attention centered on bleeding peptic ulcer.

Bleeding Peptic Ulcers

How many ulcers bleed? Figures from different parts of the world vary considerably, but it is quite generally agreed that from 12 to 20 per cent of peptic ulcers bleed at one time or another. This percentage does not, of course, include the much larger group in which the loss of blood is microscopic and relatively unimportant. In addition to the "certified" cases of bleeding ulcer there is a fairly large group included in most series of cases with gastroduodenal bleeding in which the presence of peptic ulcer has been suspected but not conclusively proved. Since the advent of gastroscopy it has been possible to segregate a considerable number of patients who bleed because of ulcerative gastritis with mucosal erosions; as a group these patients may be said to have authentic histories of ulcer and negative roentgenologic findings. During the past year a number of patients coming under this classification have been subjected to gastroscopic examination at the clinic and have been found to have erosive lesions of the stomach of such size and character as to account for the hemorrhage. It is now reasonably certain that many patients to whom the diagnostic terms "gastrostaxis" or "gastrorrhagia" have been applied are in reality the victims of hemorrhagic gastritis. Alcohol appears to figure largely in the production of this type of gastritis, as Benedict's observations show, although it is certainly not the sole cause.

---

*From the Division of Medicine, The Mayo Clinic, Rochester, Minnesota. Read before the meeting of the Minnesota State Medical Association, Duluth, Minnesota, June 30, 1938.

The pathologic changes in an ulcer which lead to hemorrhage have been discussed many times and need be considered only briefly here. Many small lesions must bleed freely at the time of their formation, as is doubtless the case with the hemorrhagic erosions found in gastritis. There is good experimental evidence to substantiate this opinion, as shown by the studies of Stalker, Bollman and Mann[35] on the formation of ulcers produced by the administration of cinchophen. Other lesions apparently bleed during the stage of healing when the bud of granulation tissue that forms at the base of an ulcer becomes injured or dislodged (Caylor).[11,12] Massive or fatal hemorrhage is most often due to erosion of an artery, usually a branch of the pancreaticoduodenal artery, lying in the base of an ulcer; this is obviously due to extension of ulceration through the submucous and muscular coats of the stomach or duodenum, a condition which is most frequently found in very active inflammatory and penetrating ulcers.

Factors Provoking Hemorrhage

A great many gastroduodenal hemorrhages appear out of a clear sky when the patient is having no symptoms of ulcer at the time; no good explanation can be offered as to why bleeding begins under such circumstances. In other cases some definite cause can often be found, of which perhaps the commonest is unaccustomed physical exertion. For instance, it is not uncommon for a patient to bleed following heavy work, lifting, violent exercise, or a long period at the wheel of an automobile; this is most often noted if the individual in question has been living a sedentary life and suddenly engages in vigorous physical activity. The abuse of alcohol is another common exciting factor, bleeding being particularly likely to occur after an episode of heavy drinking. Rivers[29] has emphasized the importance of focal and intercurrent infections in producing hemorrhagic gastroduodenitis, while Crohn and Shwartzman[16] have invoked the Shwartzman phenomenon as an explanation for the reactivation of a hemorrhagic ulcer following respiratory and other infections. In other words, there is reason to believe that certain infectious processes may produce either fresh hemorrhagic lesions or cause bleeding in a chronic ulcer.

A fourth factor relating to the cause of hemorrhage, which has only recently been considered, has to do with the possible influence of vitamin deficiency. Most patients with peptic ulcer subsist on diets which may be somewhat limited, especially in respect to fresh foods and vegetables, and there are many patients who voluntarily make even more drastic reductions in their intake of food. Many avoid citrous fruits, either because of the discomfort produced or because they feel that such fruits are "too acid" for their stomachs. Rivers and Carlson[30] have noted low levels of cevitamic acid in the blood and urine of certain individuals with hemorrhagic peptic ulcer and have also demonstrated an increase in capillary fragility in some such cases. Do these patients suffer from a latent or subclinical form of scurvy? Curiously enough, the older literature makes little reference to severe gastro-intestinal bleeding in advanced or proved scurvy except in the terminal stages of the disease. But, there are nevertheless certain well authenticated cases of gastro-intestinal bleeding which resulted from an established vitamin C deficiency, acting independently or through the medium of a peptic ulcer. Attempts have been made to determine the degree of unsaturation of the organism with cevitamic acid by the administration of large single doses and determinations of the amounts eliminated in the urine during the next few hours (Lazarus).[20] The limits of normal for this procedure have not as yet been clearly established and, consequently, figures based on this evidence cannot be taken at face value. Vitamin P, a flavone glucoside closely related to cevitamic acid, may enter into the picture since it seems to be concerned with the maintenance of normal capillary permeability and possibly with the absorption of cevitamic acid. The fat soluble, antihemorrhagic vitamin K may also be deficient in the diet of some individuals; we have recently noted one patient with recurring gastroduodenal hemorrhage who had been on a limited diet and whose prothrombin clotting time was found to be markedly prolonged. In this case the administration of vitamin K corrected the apparent prothrombin deficiency and possibly aided in the control of the bleeding.

This antihemorrhagic vitamin K is found in close association with another substance which may be of even greater importance in the genesis of bleeding from an ulcer; this is the gizzard-erosion factor, first noted by Almquist and Stokstad,[3,4] which is responsible for hemorrhagic erosion of the gizzard of chicks fed on deficient diets. Cheney[13] has recently directed attention toward the possible significance of this factor in the production of gastroduodenal hemorrhage. Much more information is required in respect to the distribution of the various vitamins in the diet of patients with ulcer and the rates of absorption under normal and pathologic conditions before a final statement on the matter can be made. It does seem, however, that vitamin deficiency may be of particular importance in the rather large group of cases of hemorrhage of indeterminate origin when a gastro-intestinal lesion adequate to explain the bleeding cannot be demonstrated. Also, the possible importance of vitamin deficiency may logically be advanced as an argument in favor of early and liberal resumption of a normal diet following hemorrhage.

The Clinical Course and Complications in Cases of Moderately Severe Gastro-Intestinal Hemorrhage.

It is well known that many bleeding ulcers are of the so-called silent type in that they produce few of the usual dyspeptic symptoms at any time. In such cases hemorrhage often appears suddenly and without warning. In older patients there may be definite prodromal symptoms of increasing ulcer dyspepsia, sometimes characterized by clinical evidence of penetration. In a minority of cases there may be minor dyspeptic symptoms accompanied by melena, with a gradual falling off of the blood count for several days before actual gross hematemesis appears.

The symptoms of massive bleeding are too well known to require elaborate description; they consist as a rule of melena, hematemesis, profuse sweating, and subsequent collapse, but not necessarily occurring in this order. The systemic evidence of hemorrhage may precede the actual appearance of blood in the stools and vomitus. Examination of the patient, seen immediately following or during an active hemorrhage, reveals little but pallor, tachycardia and hypotension, and a small pulse pressure. The rapid "thready" pulse of hemorrhage is the common expression of this last-named phenomenon. Other patients are admitted to the hospital in a condition suggesting shock. Blood counts taken on admission are extremely variable, depending on the rate of bleeding, the amount of blood lost and the previous level of hemoglobin. There may be evidence of hemoconcentration in the first specimens of blood examined, presumably because of the large amount of fluid lost with the shed blood and as a result of sweating. Therefore, the true magnitude of the hemorrhage may not be appreciated until adjustments in the body fluids have had time to occur and the normal plasma content of the blood is restored. This may explain the fact that the blood counts tend to fall even after the actual hemorrhage has ceased. In sixteen cases observed by Noth and Wilbur,[26] the average concentration of hemoglobin taken at its lowest point was 6.5 gm. per 100 c.c. and the number of erythrocytes 2,250,000 per cubic millimeter of blood; the extremes of hemoglobin variation were 3.2 and 12.9 gm., respectively, and those for the erythrocyte counts 1,200,000 and 4,800,000.

The chemical constituents of the blood often show very marked changes, consisting of a fall in plasma proteins and a marked elevation in blood urea and nonprotein nitrogen. The fall in circulating protein is comparable to that produced by plasmapheresis, although the nature of the last-mentioned condition, the so-called extrarenal azotemia, is not well understood. It has been variously attributed to dehydration, to the effects of protein destruction in the body, to a temporary falling off in renal function produced by a falling blood pressure and a reduced rate of glomerular filtration (Alsted[5,6] and Meyler[23]), and even to an actual degeneration of the epithelium of the kidney produced by anemia. Resorption of the blood from the intestinal tract appears to play a definite part in the process, as has been shown by the fact that patients who vomit most of the blood or whose stomachs have been aspirated have a less striking rise in urea than those who retain blood in the intestinal tract. Slight fever is often noted during the period when the intestinal tract is full of blood; the reasons for this are as yet unknown.

For how long a period does active bleeding persist? There is good reason to believe that in many nonfatal cases there is only one large hemorrhage. The stools, however, may show blood for several days thereafter because of the length of time required for the intestinal tract to empty itself. It is estimated that some eight to twelve days are required before the stools are negative to the benzidine test after a single hemorrhage, which incidentally, appears to be about the time required for a single dose of barium sulfate to be completely eliminated from the intestinal tract. In fatal cases, continuous or recurrent bleeding is the rule and blood may be lost with great rapidity. In other cases it may be possible to detect two or more episodes of hemorrhage a few days apart, and in still other cases, there may be evidence to show that continuous, slow bleeding is taking place.

In the case of an otherwise healthy individual regeneration of blood takes place rapidly after gastroduodenal hemorrhage. Schiødt[33] has noted that the erythrocyte count reaches a level of about 4,500,000 per cubic millimeter thirty-three days after the lowest level has been recorded, this peak being attained at about the same time regardless of the level to which the count fell. Curiously enough, he found little or no evidence to indicate that transfusion increased the rate of regeneration after hemorrhage.

The Mortality Rate of Gastroduodenal Hemorrhage From Ulcer

It is believed that in from 25 to 30 per cent of of all fatal cases of peptic ulcer death is due to hemorrhage (Monroe and Emery[24]). Figures for the mortality rate of individual gastroduodenal hemorrhages arising from peptic ulcer, however, cover the widest possible range and are, for this reason alone, extremely difficult to interpret. Babey's[7] figures are a case in point; he cited mortality figures ranging from 1 to 25 per cent in various hospitals in Europe, Great Britain, and the United States. The most probable explanation for these wide variations is that in some hospitals only patients with the more serious degrees of bleeding are admitted whereas, in others, all patients who show any signs whatever of loss of blood are taken into the hospital for observation. In order to get any accurate figures for mortality it would, therefore, be necessary to classify hemorrhages on the basis of their severity, a problem which Allen[2] and Benedict[9] have attempted to clarify.

Even with due allowance for this factor there are some sectional variations in the mortality rate from hemorrhage which are not easily explained. These sectional differences, if taken at their face value, seem to indicate that a hemorrhagic ulcer in some sections of the world is a distinctly more fatal lesion than in others. At Guy's Hospital in London only twenty-five deaths from gastroduodenal hemorrhage occurred in twenty years (Hurst and Ryle[19]), whereas the mortality rate from hemorrhage in the Scandinavian countries seems to range from 10 to 15 per cent. At King's County Hospital in Seattle, Blackford and co-workers[10] noted that the nortality rate from hemorrhage was about 20 per cent and Leon Schiff[32] has noted a 14 per cent mortality rate at the Cincinnati General Hospital. Goldman's[17] mortality figures (San Francisco) are also high (11 per cent).

The mortality rate in Minnesota hospitals and clinics seems to be definitely lower. The fatalities which we have had at the clinic are not a reliable guide since many patients with severe bleeding could hardly have been brought from any distance and the local population is too small to provide any large number of serious cases. The mortality rate at the clinic for individual hemorrhages, however, is well under 5 per cent. Regnier,[28] of the Minneapolis General Hospital's surgical staff, has kindly supplied me with figures which indicate that the mortality rate in that institution is less than 3 per cent; Noble[25] of the Ancker Hospital (Saint Paul) expresses the belief that the mortality rate at that institution was approximately 2.5 per cent. No satisfactory figures are available for Saint Mary's Hospital at Duluth or for the University Hospital (Minneapolis) but in the opinion of the consultants in these hospitals the mortality rate from hemorrhage from peptic ulcer is less than 3 per cent, which is about the estimated mortality rate on the hospital services in Rochester.

Fatal Gastroduodenal Hemorrhage.—In which locations in the body are ulcers most likely to produce fatal bleeding? There is some evidence, hardly to be considered final, to show that hemorrhage from a gastric ulcer is more likely to result fatally than one which occurs from a duodenal ulcer. Scott,[34] in reviewing thirty-nine cases of fatal hemorrhage, found that in twenty-three the bleeding occurred from duodenal ulcer, in sixteen from gastric ulcers; this is of course not in agreement with the usual ratio of ten duodenal ulcers for each gastric ulcer. Portis and Jaffe's[27] figures, taken from necropsy data, show an even greater discrepancy, twenty-two gastric ulcers and fifteen duodenal ulcers being productive of fatal bleeding. Allen's[1] figures, on the other hand, show a less striking percentage difference in mortality rate; he cited thirteen deaths in a series of ninety-four cases of hemorrhagic duodenal ulcer and six in a series of forty-two cases of bleeding gastric ulcer. Even on the basis of his figures it would appear that serious bleeding occurs more often from gastric lesions than from those located in the duodenum.

All figures on the mortality rate of hemorrhagic ulcer, in whatever location, indicate that the most serious and uncontrollable types of bleeding occur in older individuals. Goldman[17] noted that 70 per cent of all hemorrhages, fatal or nonfatal, occurred in patients past the age of forty years and that there was a definite rise in the mortality rate with advancing age and with each repeated hemorrhage. Allen's[1] figures indicate that the mortality rate from massive hemorrhage in patients past fifty, admitted to the Massachusetts General Hospital, is approximately 33 per cent.

In another paper Allen and Benedict[2] have noted that the average age at which fatal hemorrhage occurs is about fifty-six years. In short, all of the available figures indicate that fatal bleeding is relatively less likely to occur in individuals under the age of forty and is much more common in individuals over fifty. A surprising number of initial hemorrhages are fatal in these older individuals, the usual course being that of rapidly repeated episodes of massive bleeding. These repeated hemorrhages often occur within a short space of time, usually within a period of about seventy-two hours. According to Gordon-Taylor,[18] the first three days of massive bleeding will account for about 40 per cent of the deaths, 25 per cent of which will occur on the third day alone. If there is further loss of blood after the third day the mortality rate, in this author's experience, rises to 78 per cent. This is, in general, about our experience with fatal hemorrhages at the clinic. Table 1 gives the significant data in seven cases of fatal hemorrhagic ulcer recently observed at the clinic; it shows the nature and source of bleeding better than could be done by a lengthy discussion. It may be agreed, therefore, that the most severe grades of hemorrhage from gastric or duodenal lesions occur in older individuals, usually males, following a period of active symptoms of ulcer, and that the commonest pathologic finding is an active inflammatory ulcer, with erosion of an artery, often a sclerotic one, at the base (Fig. 1).

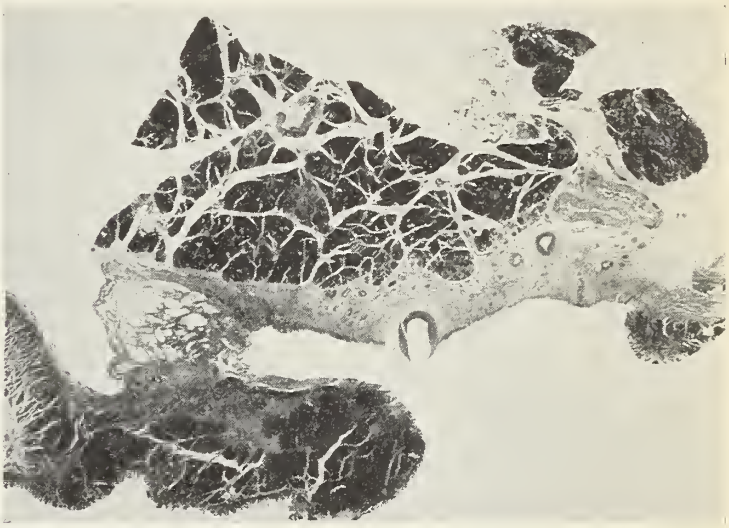

Fig. 1. Erosion of a branch of the pancreaticoduodenal artery in the base of a duodenal ulcer, with fatal hemorrhage (x2½).

Treatment of Acute Hemorrhage

On the basis of the statistics and mortality figures just cited, it is apparent that individualization of the treatment of gastroduodenal hemorrhage is essential and that routine methods of management cannot be outlined for all cases. Minor degrees of bleeding require little in the way of special therapy, rest in bed and a moderate reduction in diet being as a rule sufficient. Profuse hemorrhages raise the additional problems of maintaining blood volume and renal

TABLE I. FATAL HEMORRHAGIC ULCER

Age, years, and sex	First records after admission				Duration of ulcer symptoms, years	Previous operations	Previous hemorrhages	Source of bleeding	Remarks
	Blood pressure, mm. of mercury	Hemoglobin, gm. per 100 c.c.	Red cells, millions per cubic millimeter	Urea, milligrams per 100 c.c.					
34 M	90/60	No record	No record	No record	11	Gastro-enterostomy ten years previously; disconnected 1937.	4	Hemorrhagic gastrojejunitis.	No chronic ulcer found.
34 M	84/50	8.9	2.25	96	2	None	0	Gastric ulcer (5x3 cm.) with open vessel at base.	Persistent bleeding for one week.
55 M	60/?	10.2	3.73	28	18	None	1	Hemorrhagic inflammatory duodenal ulcer (2x1.5 cm.). No open vessels.	Bled persistently one week. Pyloric obstruction on admission.
58 M	70/40	6.2	2.52	58	15	Gastro-enterostomy 1931 and excision of gastrojejunal ulcer 1934. Partial gastrectomy 1937.	0	Ulcer in duodenal stump with erosion of large artery.	Typical ulcer formed with very active inflammatory ulcers. Died fourth day after bleeding began.
62 F	96/60	6.0	2.22		13	None	0	Duodenal ulcer (1.8x2.7 cm.) with open artery at base.	Survived twenty-two days after bleeding began.
60 M	94/40	5.7	3.48	60	15	None	3	Large duodenal ulcer with open artery at base.	Survived fourteen days after bleeding began.
68 M	86/70	17.0	5.0	102	20	None	0	Large (6x10 cm.) serpiginous ulcer in stomach. Perforating duodenal ulcer (1.5x1 cm.) with open artery.	Renal insufficiency and gangrene both legs. Lived ten days after bleeding began.

function, while massive or arterial hemorrhage can hardly be controlled except by a direct surgical attack. Unfortunately, one cannot at the onset of hemorrhage predict with any certainty the degree of bleeding which may eventually be attained. The best plan is to be prepared for serious loss of blood. For this reason each hospital should establish a definite organization and a general plan of management for cases of hemorrhage since such standardization of the methods of approach may result in the saving of lives. The necessity for routine orders covering such matters as the frequent recording of blood pressure, pulse and blood counts is apparent and a blood grouping and estimation of blood urea should be carried out without delay. Apparatus for the administration of fluids subcutaneously or intravenously should be instantly available, since the circulating fluids of the body may be maintained in this manner until a transfusion can be arranged.

Often the first consideration in cases of active bleeding is the treatment of shock. The foot of the bed should be elevated, the patient should be kept warm, and sedatives (usually morphine) should be administered. Later, pentobarbital sodium (nembutal) or other barbiturates may suffice. The traditional ice bag to the abdomen is probably unimportant. If the patient is in severe shock, infusion of a solution of 6 per cent acacia may be employed as a temporary substitute for blood. The restoration of lost body fluids is obviously important since the loss of fluid in these cases is large, particularly because of the profuse sweating and diarrhea which so commonly accompany hemorrhage; in older individuals the danger of extrarenal azotemia or even renal insufficiency is large. As Noth and Wilbur[26] have noted, fluids are best given subcutaneously, but once active bleeding has ceased, the intravenous route may be employed, particularly if the output of urine falls off markedly and if the blood urea rises. Until such time as fluids can be given by mouth, at least 2 to 3 liters of fluid is a minimal requirement.

Transfusion.—One of the most obvious and important immediate steps to be taken is to provide for a generous number of blood donors from among the patient's relatives and friends, since there are few patients with profuse hemorrhage from ulcer who will not require the administration of blood at some time. The rationale of employing blood transfusion in the treatment of active gastroduodenal hemorrhage has been considered by many writers. One school feels that transfusions should be withheld in order that a rise in blood pressure may not dislodge any newly formed thrombi at the site of hemorrhage; obviously if severe or massive bleeding occurs this need not apply because of the absolute necessity of preventing exsanguination. Most authorities on the subject now believe that the danger of transfusion increasing the rate of blood loss is small and that there are more lives lost by withholding transfusion than by overdoing the administration of blood. In many hospitals, massive transfusions by the drip method are now employed according to the method of Marriott and Kekwick.[21] These authors advocate the administration of blood by continuous venoclysis at a rate that will produce a 10 per cent rise in the concentration of hemoglobin in each four-hour period. Translated into terms of blood administered, this amounts to from 100 to 135 c.c. of blood per hour; 4 or 5 liters, or even more, of blood may be given over a period of forty-eight hours or longer. Such large amounts of blood require a "blood bank," or an unusually generous supply of donors, but they may be lifesaving measures in cases of massive hemorrhage. Not many patients will require these massive transfusions, but there are hardly any individuals who have sustained even a moderately severe loss of blood who will not be greatly helped by the administration of one or several small transfusions (250 to 350 c.c.).

Gastric Lavage.—The use of this procedure to determine the rate of blood loss and to apply coagulants directly to the site of hemorrhage has been both endorsed and decried. It has been suggested that a catheter be introduced into the stomach with the idea of determining whether or not arterial blood is present. If bright blood continues to flow through the catheter one may suspect erosion of a large artery. This is probably a useful point. The administration through the intragastric tube of ice water, epinephrine, and other substances to produce coagulation, is of very doubtful value. Recently, the use of snake venom as a hemostatic has been advised, but no data have been presented to prove its merit. Wangensteen[36] has employed intubation of the stomach with suction attached, chiefly because of the danger of acute perforation in the case of an actively bleeding and inflammatory ulcer; this danger, however, is admittedly small (2 to 3 per cent).

Diet.—How long should food be withheld after a hemorrhage? It was formerly the practice to give nothing by mouth for at least four days or until the stools were free of blood, but this plan of treatment is gradually being abandoned. Meulengracht[22] was the first to suggest the early and liberal administration of food; he claimed a very substantial reduction in the mortality rate as a result of this innovation. His method of procedure is rapidly gaining favor for three reasons: (1) a well-filled stomach, according to Christensen,[14] has considerably less peristaltic activity than an empty one; (2) in the patient with no involvement of a large vessel bleeding is probably self-limited, the administration of food, therefore, serving only to hasten convalescence and to take care of any protein depletion or vitamin deficiency which may have existed, and (3) the patient with an open artery is not harmed, since bleeding will continue to occur no matter what is done.

A great many conservative clinicians and gastro-enterologists have been impressed with the Meulengracht treatment and it is now being adopted, with some modifications, in this country. It has been our practice at the clinic to withhold food for from twenty-four to forty-eight hours or until such time as evidence of rapid loss of blood is no longer apparent. After this period, small hourly feedings of ice water, gruel, milk, and sweetened fruit juices are allowed and, if no further bleeding occurs, the patient is allowed to take a generous soft diet in the form of five or six feedings at appropriate intervals on the following day. Alkalis may or may not be administered, depending on whether or not ulcer pain is present.

The Surgical Treatment of Massive Hemorrhage

Any discussion of surgical treatment in relation to bleeding ulcer involves two considerations: (1) the problem of the individual with recurrent hemorrhage, and (2) the matter of surgical intervention in the face of acute bleeding. The first consideration is beyond the scope of this discussion, but it may be said briefly that the age of the patient, the frequency and severity of the hemorrhages, the interval between them and the circumstances associated with each, must be taken into account and that each case represents an individual problem for which no hard and fast rules can be established. The most reliable treatment for repeated and severe hemorrhage from peptic ulcer is partial gastric resection; more conservative measures, such as gastro-enterostomy or pyloroplasty, fall short of the mark and, in fact, even with large resections the protection against hemorrhage is not absolute. Gordon-Taylor's[18] recent paper may be recommended as the best expression of surgical opinion on this debatable subject.

The question of surgical intervention in cases of acute hemorrhage has been well discussed by Balfour[8] in a recent editorial. The objections to a direct surgical attack on the bleeding point under these circumstances are four in number: (1) no actual ulcer may be present, or even if it is, it may not be found; (2) conservative procedures like gastro-enterostomy are inadequate to prevent further loss of blood; (3) the risk of resection, the only relatively certain method of attack, is almost prohibitively high under these circumstances, and (4) if more than three or four days have elapsed since the first hemorrhage, the risk even for simple exploration and ligation of vessels in the vicinity of the ulcer reaches formidable proportions. In favor of surgical intervention it may be said: (1) that there is no other way of controlling the bleeding from an open artery; (2) the mortality rate of conservative medical treatment in cases of severe bleeding, particularly in older individuals, is also extremely high; (3) that if subacute perforation or obstruction are present these can be dealt with surgically, and (4) it is often possible to get patients into very satisfactory condition by the continued use of the drip method of transfusion and the continued transference of large quantities of blood, extensive surgical procedures thus being made possible. We at the clinic have had some recent successful experiences with direct attack on an uncontrollable bleeding ulcer; other workers, including Allen[1] and Gordon-Taylor,[18] have felt that such radical steps are taken too infrequently.

No indications for surgical intervention can be laid down for the treatment in any individual case; suffice it to say that a surgeon should be called in consultation in cases of actively bleeding ulcers and that all preparations should be made for surgical interference in the event that bleeding continues. This requires a high degree of courage and decision on the part of the surgeon as well as careful organization of both the medical and surgical services of the hospital in question and the availability of large amounts of blood for transfusion. Early surgical intervention is much to be preferred once a decision is made as to the probability of arterial bleeding. In fact, there are many surgical authorities who feel that a direct surgical attack on the bleeding ulcer is rarely successful after more than forty-eight hours have elapsed since hemorrhage began.

Summary and Conclusions

The clinical course, mortality rate, complications and treatment of acute gastroduodenal hemorrhage have been considered. The available evidence indicates that serious bleeding occurs in from 15 to 30 per cent of cases of peptic ulcer and that it is probably responsible for about 30 per cent of all deaths from peptic ulcer. Fatal hemorrhage is chiefly due to the erosion of large and arteriosclerotic vessels in older patients. Under these circumstances the only hope of saving the patient is direct surgical attack on the bleeding lesion. Serious hemorrhage also may arise from relatively insignificant lesions of the stomach and duodenum, some of which may form on the basis of minor inflammatory lesions of the mucosa whereas others may depend on vitamin deficiencies. The treatment of such lesions is preferably conservative.

The Meulengracht method of treatment, that is, a liberalization of diet and early feedings after active hemorrhage has ceased, has many advantages in the management of such cases. The difficulties, of course, are that the nature of the local lesion and the type of bleeding occurring from it cannot be determined with any certainty except in a relatively small group of cases. The duration of the individual hemorrhage, the age factor, the previous history and the availability of proper facilities for maintaining the blood at a point above the level of exsanguination often influence the decision as to the desirability of a direct surgical attack.

Discussion

Dr. P. W. Harrison, Worthington: I am glad to have the privilege of discussing the very excellent paper just read by Dr. Snell. Hemorrhage of any type is very dramatic and frequently most alarming to the patient and his family, as well as to the physician.

Dr. Snell has shown that the probable incidence of serious bleeding as a complication of peptic ulcer is between 15 and 30 per cent. He has also presented what statistics are available for the Minnesota area, which tend to show that in this region fatal hemorrhage occurs in less than 5 per cent of the cases observed. He has also indicated the general agreement that fatal hemorrhage is chiefly due to the arrosion of large arteries, particularly in sclerotic vessels in older patients.

Goldman reported that at San Francisco Hospital 70 per cent of all hemorrhages from peptic ulcers occurred in patients over forty years of age, and that fatal hemorrhage was rare before the age of forty. He, too, stressed that exsanguination usually was the result of bleeding from a large artery, particularly in the presence of arteriosclerosis.

While each case must be individualized, it would appear that the need for immediate surgical intervention is most likely to be definitely required in this older group with continued or repeated hemorrhages. Surgery in this group of cases is likely to be a very formidable procedure. First, the patient is a bad risk because of lowered resistance from his bleeding. Second, too frequently the only procedure which offers any hope of relieving the situation is a radical removal of the ulcer bearing area at a most unfavorable time, because of the accompanying inflammation and edema. This is particularly true of those ulcers on the posterior wall of the duodenum.

It would appear that the immediate treatment of the majority of cases of bleeding from duodenal or gastric ulcers will be conservative.

The first concern is frequently the treatment of shock. The usual external heat and sedatives are important. If the shock is severe, gum acacia may be used intravenously to support the blood volume. However, I would stress the immediate provision of donors. If the appearance of urgency continues, I believe that either repeated small blood transfusions (125 to 300 c.c.) should be given or after the first one or two transfusions, the drip method of Marriott and Kekwick be instituted. With threatened exsanguination, there of course can be no dispute about the value of transfusion, but even in those hemorrhages of lesser degree, it would seem that more good than harm can be accomplished by slow transfusion, both for the replacement of blood and for any possible hemostatic effect. I believe that the most common error is in expecting too much from one or two small transfusions.

The generally accepted medical treatment of these cases includes starvation for twenty-four to forty-eight hours, or even longer, and then a prolonged period with a greatly restricted diet, accompanied by the use of alkalies.

Meulengracht has introduced the idea of early liberal feeding of finely minced food. He offers a series of 273 cases of pure ulcers and erosion treated for hemorrhage in which early liberal feeding was used and states that the mortality rate has been reduced from an expected 8 to about 1 per cent. He doubts that food has any hemostatic effect, but believes that general exhaustion and the effects of anemia accentuated by starvation, lack of water, salts and vitamins are greatly reduced by feeding.

Boyd and Schlachman of New York have a small series of cases which they feel tends to corroborate Meulengracht's findings. They also present evidence to show that with this regimen there is more prompt relief of subjective symptoms, quicker regeneration of blood and a definite shortening of the period of disability. This work is impressive enough to warrant very serious consideration.

HEART DISEASE IN PREGNANCY*

JOSEPH F. BORG, M.D.
Saint Paul, Minnesota

WHILE the risk of child-bearing in the cardiac patient has been markedly reduced in recent years, the mortality of pregnancy associated with heart disease is still three times as great as that of uncomplicated pregnancy. There is much reason to believe that this situation is entirely unnecessary and can be markedly improved by intelligent medical management.

The marked increase on the burden of the circulation which occurs in pregnancy has long been recognized.[1, 11, 13] Only recently has the true extent of this been known and the contributory factors demonstrated. Most of these enter into consideration after the fourth month. Naturally prominent among them is the increase in metabolism of about 15 per cent, associated with an increased thyroid activity. The heart rate is elevated fifteen to twenty beats per minute. The venous pressure in the pelvis and legs is definitely increased. The circulating blood volume becomes demonstrably enlarged and there is a gradual increase in the minute volume output, amounting to about 50 per cent at term.[17] This may increase further during labor, but gradually recedes to normal about four weeks post partum. An important factor not generally considered is the development of large new blood channels in the placenta, over which a bruit may be heard. These act similarly to an arteriovenous aneurysm in increasing the heart burden.[1] As a result of these stresses may be explained a definite enlargement of about 10 per cent in the heart size. This appears even larger in the teleoroentgenogram due to the upward displacement of the diaphragm in the later months of pregnancy.

These conditions are continuous burdens on the resting heart. They have been shown to throw their maximum strain on the circulation at about the seventh month, at which time the greatest danger of myocardial embarrassment exists. They are well borne by the normal organ and heart failure does not occur, but where heart disease is present the patient may not be able to retain her compensation or the reserve may be so narrow that seemingly innocuous factors may precipitate its breakdown.

Owing to the fact that about 10 per cent of pregnant women present symptoms or signs which may suggest the presence of heart disease while only about 2 per cent actually have such a disorder,[7] careful study is necessary to distinguish the latter cases. Breathlessness at accustomed tasks, haphazard chest pains, dizziness, palpitation, faintness, systolic murmurs, edema, increased heart size, altered heart tones and increased pulmonary markings may all be noted in pregnant women with normal hearts.[7, 8] When due to cardiac disease these will disappear after delivery unless a neurocirculatory asthenia remains to account for some of the symptoms. Significant of heart disease is the presence of more marked cardiac enlargement with characteristic outline changes, diastolic murmurs associated usually with a definite history of a probable etiologic factor, and often some of the other signs and symptoms mentioned.

---

*Read at the annual meeting of the Minnesota State Medical Association, Duluth, Minnesota, June 29, 1938.

As is to be expected in the age group considered, rheumatic heart disease predominates markedly, comprising about 95 per cent of all pregnant women with heart trouble.[2] About 2 per cent have congenital heart disease of various types. The remainder are accounted for by the rare cases of hypertensive heart disease, subacute bacterial endocarditis, hyperthyroidism, and the few of indeterminate origin. Of those with rheumatic heart disease the great majority have mitral stenosis, uncomplicated or with aortic valve disease, and a few have aortic valve disease alone.

After the diagnosis of heart disease has been made, the problem of management must be approached. This can be considerably facilitated by employing the functional classification of the American Heart Association as shown in Chart I. Regardless of the anatomic or etiologic diagnosis, this classification will prove of marked value, although it has its limitations. These are illustrated by the fact that the patient may shift from one class to another while under observation, and there are borderline cases where differences of opinion will exist among different observers regarding their class designations.

Of greatest importance in the recognition and treatment of these patients is the prenatal care.[17] About half of them enter pregnancy unaware of the presence of heart disease. Examination in the early months may enable the diagnosis to be made more easily since the rather common symptoms which may be confused with heart trouble do not usually appear at that time. Once diagnosed, proper management and advice will markedly reduce the chances of cardiac embarrassment in the later months of pregnancy when the burden on the heart is much greater. The importance of such care is shown in the observations of Lamb,[12] who reports a mortality of 20 per cent where the patients were first seen in a decompensated state and 2.2 per cent in the group where compensation was good. Fitzgerald[5] reports no mortality in 192 pregnancies associated with serious heart disease. Scott and Henderson[16] report double the incidence of cardiac failure in charity clinic patients as compared with private patients. The results of all other workers attest to this situation and fully justify the earlier statement to the effect that mortality among pregnant cardiac patients should be little different from the average mortality in pregnancy.

CHART I. AMERICAN HEART ASSOCIATION FUNCTIONAL CLASSIFICATION

I. Patients with organic heart disease able to carry on ordinary physical activity without discomfort.
II. Patients with organic heart disease unable to undertake ordinary physical activity without discomfort.
    (a) Activity slightly limited.
    (b) Activity greatly limited.
III. Patients with organic heart disease and with symptoms or signs of heart failure when at rest, unable to undertake any physical activity without discomfort.

Patients falling in class I and IIa seldom have serious difficulty going through delivery. Nevertheless they are not immune to the precipitating causes of heart failure which may throw them into class IIb or class III, where their management is a very serious matter, and a high mortality exists. This eventuality should never occur with proper handling of the patient who will cooperate. Decompensation rarely occurs without a definitely demonstrable precipitating cause,[1] such as over-exertion, mental overstrain, and infections with their tachycardia and fever. These are important to avoid. Also to be recognized for the increased burden which they put on the heart and for their amenability to treatment are such conditions as anemia, obesity, and dietary deficiencies, especially Vitamin B. If these patients carry through the seventh month, the period during which the circulation is under most severe strain,[11] a normal delivery should be effected without signs of undue cardiac embarrassment. However, extremely cautious prenatal observation and advice for all these women is necessary, since there are no criteria by which the patients who are most likely to have trouble can be selected. Of prime importance to be stressed is the need for frequent observation from early pregnancy. The patient should report every two weeks to the sixth month, and weekly thereafter, with instructions to inform the physician at any time if undue fatigue, dyspnea, edema, palpitation or cough are experienced. This must be emphasized because when failure appears it is often sudden in its onset. The need for sparing the circulation through adequate rest and avoidance of shopping tours, limitation of stair climbing, and restriction of weight gain are important. The strain of receiving visitors, family illness, household moving, etc., are not to be forgotten. To bed with any intercurrent illness, after calling the physician, is a strict rule. During the seventh and eighth months all activities should be even more limited.

At the periodic examinations keen judgment is sometimes required to ascertain the significance of symptoms which may be given. More definitely indicating the onset of failure are the appearance of basal râles in the lungs, cough, prominent jugular pulsation, liver tenderness, marked weight gain and paroxysmal dyspnea. Effort tests and vital capacity determinations in the latter months may be misleading. Should decompensation appear, absolute bed rest with the usual regime of treatment of heart failure is indicated. As a rule the patients respond well.

Even if no suggestion of myocardial overstrain appears in the class I or IIa patients, they should still be placed in the hospital if possible two weeks before anticipated delivery,[17] or a very strict home care pursued. Labor is usually carried through without difficulty, although forceps delivery, after full cervical dilatation, is indicated if there develops a heart rate greater than 115, or a respiratory rate over twenty-eight.[4] A curve of the latter two observations charted at ten minute intervals during labor will be of value in pointing to the onset of undue myocardial fatigue. A rising curve, especially if associated with dyspnea, may be the forerunner of a severe decompensation. If full dilatation has not occurred, any interference will only aggravate the situation. Morphine must now be used for rest, and the usual treatment of heart failure instituted.

Treatment of class IIb and class III patients is much more difficult for it is among these that almost the entire mortality from heart disease is found. Women whose heart condition has ever justified such classification prior to pregnancy should never become pregnant, and those who enter these groups after becoming pregnant have either been poorly advised or unable for some reason to follow instructions. Patients seen in the first trimester who have previously had decompensation or who enter pregnancy in this state should not be permitted to carry on to delivery,[3] and therapeutic abortion is advised before the fourth month, after the decompensation has been treated in the usual manner. Further pregnancy should be made impossible in these patients.

Class IIb patients seen later than the third month require careful observation, much rest, and medication directed toward supporting the heart. If there is no history of congestive failure and the patient is a multipara, spontaneous delivery usually is effected. If this patient goes into class III the failure is treated, and if successful, cesarean section is justified at term.[10, 15]

Class III patients first seen beyond the third month are treated likewise. Medical treatment of the heart failure is most important. Delivery of this class of patients by any known method carries more than 50 per cent mortality,[4, 9] and operative interference is nearly always fatal. If these patients fail to respond to medical treatment, therefore, their interests are best conserved by letting nature take its course,[12] and permitting spontaneous delivery in bed. Rest periods effected by morphine are indicated in such conditions.[4] It can thus be seen that the serious problems are those brought about by delay in reporting for prenatal care, and are therefore to be considered usually preventable.

The question of sterilization always[4, 17] arises when dealing with class IIb or class III patients, whether first seen in those classes or otherwise. Numerous observers advise it when cesarean section is performed, or later. Many factors,[17] religious, social and economic, must be considered when this problem arises, but in any event further pregnancies should be most emphatically discouraged.

The choice of anesthesia in the cardiac patient will depend on the skill and experience of the anesthetist.[13] Ether is widely used, but ethylene,[1] cyclopropane, and spinal anesthesia are proving quite satisfactory.

The prognosis for the pregnant woman with heart disease is good provided competent medical supervision is followed. The knowledge that rarely does a class IIb or class III patient fail to respond to treatment in the first attack of decompensation, and that the deaths are practically always those with heart failure histories, points to the fact that this problem should not be too difficult to handle. Every woman with heart disease is entitled to one or two children[6, 18] provided she has not had a cardiac breakdown, and is economically so situated that the raising of a family is not judged to be too great a burden. However, certain patients should never become pregnant, and, if they do, interruption is justified. This obtains where there is a history of heart failure,[3] presence of auricular fibrillation,[7, 11] signs of serious heart muscle damage in the electrocardiogram, active endocarditis or serious complications as tuberculosis, hypertension or nephritis. To such patients should be stressed the danger of further pregnancies, and contraceptive advice or sterilization may be seriously considered.

It has been definitely shown that the age of the patient is an important factor in the chance of carrying through a normal pregnancy, women over thirty-five years of age displaying a markedly higher death rate.[2] Studies on the remote effect of pregnancy on the heart diseases are extremely difficult and no convincing conclusions have been reported, although those who express an opinion are satisfied that repeated pregnancies tend to reduce the span of life and increase the danger of death from heart failure.[6, 9] It is safe to say that "any patient with organic heart disease should be regarded as a case of potential heart failure, because there is no known formula to tell which cases will go through safely and which will not."[3] Many of these women will carry safely through pregnancy but sustain increased heart damage. Frequently repeated is the opinion that the cardiac patient has an easy delivery. Careful observation does not bear this out. Most important in the matter of prognosis is the fact that it can be greatly determined by the coöperation of the patient and intelligent management by the physician.

Finally, it may well be emphasized that here we are dealing with a problem which often requires a great deal of intelligent thinking and keen judgment. This is most satisfactorily provided where it is possible to have the coöperating observation of the cardiologist and the obstetrician, as it has been repeatedly shown that the best results in handling these situations have been obtained where such coöperation existed.

Summary

1. The nature of the increased load on the heart in pregnancy and its significance when that organ is diseased are discussed.
2. The presence of many signs of heart embarrassment in patients without heart disease is pointed out and the separation of these women from those affected by heart disease is shown to be of importance.
3. The problem of heart disease in pregnancy is chiefly that of the rheumatic heart.
4. Classification of these patients according to the functional classification of the American Heart Association will greatly aid in the management of the individual case.
5. The significance of heart disease in any pregnant woman is determined in great part by the character of the prenatal care, the most important element of treatment.
6. Management of these patients consists primarily in considering each an individual problem. The functional classification aids in determining the measures to be employed.
7. Heart failure in pregnancy is treated in the usual manner. Its effects on the pregnancy vary in seriousness with the therapeutic response of the decompensation.
8. The prognosis of heart disease in pregnancy should be good under proper management with no significant increase in mortality.

Discussion

Dr. E. M. Kasper, Saint Paul: It is altogether fitting that the subject of heart disease and pregnancy should be presented by an internist, for a woman who presents herself with these two conditions should be considered as a case of heart disease complicated by pregnancy and not as pregnancy complicated by heart disease.

As usual, Doctor Borg has very ably presented his subject. Every sentence contains much meat which must be digested, and I believe that all of us should read carefully all that he has said when his article is published.

In this condition, we again find what can be accomplished by adequate prenatal care. The mortality rate which used to be above 10% has now been reduced to nearly 2%. Nevertheless, heart disease still ranks high in the causes of maternal deaths, about fifth, I believe. Nearly 1,000 mothers die each year from this condition in the United States alone!

Because many women do not realize that they have heart disease, a great responsibility falls on the obstetrician to discover its presence. Anyone can diagnose easily cardiac decompensation, but when that occurs it often is too late to be of much help, for at least 50% of these women die. Instead, it is up to the obstetrician who firsts sees this patient to be able to differentiate between a normal and an abnormal heart during pregnancy and so be able to get the abnormal heart under treatment early.

Rarely will a cardiac patient ask our advice as to whether she should get married, and it is not common to have a married woman with cardiac pathology ask whether she should have children. What more commonly happens is that a cardiac patient who is pregnant will want to know if she can carry safely through her pregnancy. Such problems must be very carefully considered and all factors must be weighted before an answer can be given. Close coöperation between patient, obstetrician and cardiologist is necessary in order to come to the correct conclusion.

The heart specialist should share in the care of an obstetrical patient with heart disease throughout pregnancy, labor and the puerperium. It is very hard to generalize, in considering these cases, for every case should be individualized. However, I believe that a woman who has not suffered from decompensation should be able to carry through a pregnancy to or near term. The question of an interruption of pregnancy so often arises but, using the words of Jensen in his excellent book, The Heart of Pregnancy,—"It (abortion) should now rarely be performed, for either a woman should not undertake pregnancy or she should be capable of carrying it through."

Heart failure is the indication for interruption of pregnancy but under no circumstances should interruption, whether early or late, occur when decompensation is present. If failure occurs before the 16th or 18th week, an abortion should be done. If later, it may be deemed advisable to carry the patient until the fetus is viable. Delivery is performed in the manner which is easiest for the mother and child, and at this stage, I prefer cesarean section. However, most cardiac cases are carried to term without trouble developing, but it is during labor that decompensation is most likely to occur. The obstetrician and the cardiologist must both be in constant attention at this time.

If no signs of cardiac embarrassment are encountered, usually routine procedures of labor can be followed, but if symptoms of cardiac trouble develop, the patient must be rested as much as possible, treated medically by the heart specialist and forceps applied after complete dilatation of the cervix is accomplished in order to spare the mother expulsive efforts. Occasionally early in labor, a cesarean section might be done though rarely is this necessary.

Our problem does not stop in the delivery for strict observation should be continued during the puerperium. If any interference has been necessary, there is an increased danger of infection, hemorrhage and shock. When there has been no decompensation, there is no contra-indication to lactation.

I would like to recommend to every one the recently published book by Julius Jensen. He has very thoroughly covered every angle of this subject.

FOREIGN BODIES IN CORNEA: CARE AND COMPLICATIONS

W. T. WENNER, M.D.
St. Cloud, Minnesota

FOREIGN body in the cornea is the most frequent eye injury encountered. In an analysis of injuries occurring in industry it comprised 60 per cent of all cases. For this reason it should merit most careful consideration.

In examining an eye for injury, it is paramount to have good illumination and proper magnification. This applies to the detection and removal of corneal foreign bodies. Before removing such a foreign body, the cornea should be thoroughly anesthetized. The ideal drug for topical anesthesia should be non-irritating, not drying to corneal epithelium, and should not cause dilatation of the pupil, but at the same time it should give good anesthesia. Cocaine is not a good anesthetic as it causes drying of corneal epithelium and dilatation of the pupil. There are various solutions on the market that most nearly meet the above requirements: butyn, metycaine or nupercaine in two per cent solution, and pantocaine in one-half or one per cent solution. Three to four instillations, allowing a few minute intervals between instillations, usually give sufficient anesthesia. It is only in the highly inflamed eye that more instillations are required.

After good anesthesia has been obtained, the foreign body is removed. The instrument of choice for removing a corneal foreign body is a sterilized sharp spud. This allows clean removal with a minimum of damage to the remainder of corneal tissue. If the foreign body is magnetic, one should use the magnet.

If the foreign body is iron, it is readily disintegrated into the ferric salts which are irritating to corneal tissue. In removing this type of foreign body, it is essential to remove the brownish red pigmentation and the layer of oxidized tissue surrounding the foreign body. This is best accomplished with a corneal burr. One can use an ordinary dental burr with fine markings fitted into a chuck handle, rotating it between thumb and fingers directly over the foreign body crater. It will smooth the edges of the crater, add to the patient's comfort and lessen the dangers of corneal ulcer developing. After using the burr in these and similar cases, less postoperative reaction follows and a definite decrease is noted in the incidence of the infiltrative type of ulcer. These are the cases in which, following removal, the patient returns in a day or two with a red eye and infiltration at the site of the foreign body. This is most frequently due to incompletely removing the slough immediately surrounding the foreign material, and for this reason the use of the burr is recommended.

TABLE I.

1,069 Cases		Average Elapsed Time from Injury to First Treatment
Total number foreign bodies	1,663	1.96 days
Number uninfected foreign bodies on first examination	1,476	1.37 days
Number foreign bodies with ulcer present on first examination	187	7.00 days
Number ulcers following foreign body removal	27	1.5 days

After the foreign body has been cleanly removed, it is good practice to instill an antiseptic ointment which contains some type of an anesthetic—butyn-bichloride, butyn-metaphen, or metycaine-merthiolate—and apply an eye pad firmly. The patient is advised to leave the pad in place over night. Experience has shown that this type of dressing results in more comfort, less irritation, less manipulation on the part of the patient, and therefore, more prompt healing and fewer complications. When the patient has only one seeing eye, it is not practical to apply the above dressing, in which case instilling the ointment usually suffices. Some oculists advocate in these cases the application of a minute amount of carbolic acid to the denuded area with a sharpened wooden applicator, care being taken to remove all the excessive acid from the applicator to prevent its spreading to the clean cornea. If the eye shows any inflammatory reaction, the pupil is always dilated with homatropine or atropine, depending upon the age of the patient.

All corneal wounds should be considered serious until proven otherwise by healing. The danger of any corneal injury is corneal ulcer with a resulting scar, or an extension of the infection to the inner structures of the eye with resulting perforation sometimes necessitating enucleation.

What is the pathogenesis of corneal ulcers following the removal of a superficial foreign body? All foreign material in the cornea should be removed promptly to prevent inflammation, sloughing and ulceration of the surrounding layers of tissue, which represent nature's method of accomplishing removal of foreign bodies if left undisturbed. The material that caused the injury may itself inoculate the cornea directly with bacteria. Ordinarily, however, one has to deal with a secondary invasion of bacteria into the small wound, for the infection is generally caused by bacteria which scarcely ever are found on the foreign bodies that cause the injury, but are found very commonly in the conjunctival sac. For this reason, in all cases where corneal epithelium is broken—as from an abrasion or foreign body—the lacrimal drainage system should be inspected. If the tear sac is infected it should be removed, or if this is impractical, precaution should be taken to render it as free from danger as possible. The puncta

TABLE II. DISTRIBUTION OF FOREIGN BODIES OF THE CORNEA ACCORDING TO OCCUPATION

Occupation	Number Foreign Bodies	Percentage of Total Foreign Bodies (1,663)
Granite	652	39.2
Industry Hilger, Iron, Pulp, Paper, Diamond, Aluminum	328	19.8
Farm	143	8.6
Laborer	131	7.9
Student	93	5.6
Railroad	64	3.8
Mechanic	60	3.6
Clerical	41	2.4
Housewife	28	1.7
Miscellaneous Teachers, Children, Salesmen, etc.	123	7.4
	1,663	100.0

TABLE III. INCIDENCE OF ULCERS FOLLOWING TREATMENT OF FOREIGN BODIES ACCORDING TO OCCUPATION

Occupation	Number Foreign Bodies	No. Ulcers Following Treatment	Percentage
Granite	652	12	1.8
Industry	328	4	1.2
Farm	143	2	1.3
Laborer	131	1	0.76
Student	93	1	1.07
Railroad	64	2	3.1
Mechanic	60	2	3.3
Clerical	41	1	2.4
Housewife	28	0	0.0
Miscellaneous	123	1	0.81
	1,663	27	
	Average incidence, 1.62%		

TABLE IV. INCIDENCE FROM FOREIGN BODIES ON FIRST EXAMINATION ACCORDING TO OCCUPATION

Occupation	Number Foreign Bodies	Number Ulcers Present	Percentage
Granite	652	42	6.4
Industry	328	23	7.0
Farm	143	42	29.3
Laborer	131	14	10.6
Student	93	21	22.5
Railroad	64	7	10.9
Mechanic	60	7	13.3
Clerical	41	4	9.7
Housewife	28	5	17.8
Miscellaneous	123	21	17.0
	1,663	187	
Average incidence, 11.2%			

in many of these cases may be sealed by actual cautery.

What is the ulcer incidence after removal of corneal foreign bodies, as well as the incidence of ulcers in foreign body cases when first seen with a corneal foreign body present? The following is a review taken from our records over a period of ten years. These foreign bodies were removed either by the late Dr. John J. Gelz, Dr. Joseph B. Gaida, or by myself.

Incidence of Ulcers from Non-perforating Foreign Body Injuries of the Cornea

The number of patients seen with foreign bodies of the cornea in the last ten years has totaled 1,069; the total number of foreign bodies, 1,663. Many of the industrial employees have had repeated injuries.

The average time that these 1,663 foreign bodies were seen after the injury was sustained was 1.96 days.

Twenty-seven or 1.62 per cent of the 1,663 foreign bodies, were accompanied by ulcers following examination and treatment. The surprising factor here is the time elapsing between injury and the time attention was sought, an average of 1.5 days. Of the twenty-seven ulcers eleven were of the infiltrative type and sixteen of the foul type of ulcers.

Of these 1,069 patients, 175, or 16.3 per cent, had a total of 187 ulcers already present when attention was first sought. This gives an incidence of 11.2 per cent in the 1,663 foreign body cases. Eight of the 175 patients had a total of twenty ulcers in this time period. The average elapsed time before seeking medical attention in the cases where ulcers were found on first examination was exactly seven days, as compared with the average of 1.37 days of group without infection.

There were sixty-five of the infiltrative type, and 122 of the foul type of ulcers seen in these 187 cases. Two of these ulcers perforated, and one finally necessitated an enucleation. One required a Sæmisch incision which also resulted in a total loss of vision.

Twenty-three per cent of the patients that presented themselves with ulcers present at first examination had been seen and treated by someone previously and were referred because of irritated, red eyes. Many of these had the infiltrative type of ulcer resulting from incomplete removal of the foreign body. They cleared promptly on using the burr and cleansing the foreign body crater.

The striking significance of these tabulations is that the lowest incidence of ulcers is in granite and industrial workers which are compensation cases and are instructed to seek medical aid as soon as an injury occurs. Even in these, many instances are found where fellow workers attempt removal, and only if the eye continues to irritate do they seek medical attention. The incidence is highest in farmers and students where delay in seeking attention is the greatest.

TABLE V. INCIDENCE OF OPACITIES RESULTING IN VISUAL LOSS

Forty-nine opacities in a total of 214 ulcers	22.9%
Forty-nine opacities in a total of 1,663 foreign bodies	2.9%
Three opacities in 27 post-treatment cases	11.1%
Forty-six opacities in 187 pre-treatment cases	24.6%
Three post-treatment opacities in 1,663 foreign bodies	0.18%
Forty-six pre-treatment opacities in 1,663 foreign bodies	2.70%

Opacities reported are only those involving the pupil area and those that resulted in visual loss, which varied from 5 per cent to total loss. These figures bring out that visual loss incidence was greatest in patient having an ulcer present when the patient reported for treatment. Usually a period of three to nine months was allowed to elapse before recording the final loss, as in many instances superficial macula would thin, resulting in improved vision. The total incidence of loss for the entire series as seen in above figures is 2.9 per cent, which is comparatively small.

Conclusions

1. Foreign bodies in the cornea should be treated as surgical emergencies.

2. Ulcer incidence following foreign body injury to the cornea is more frequent in patient having a foreign body present over a period of time.

3. The highest incidence is in farmers and farm workers.

4. The lowest rate is in industrial workers. These patients are required to report early for treatment.

Discussion

Dr. E. P. Burch, Saint Paul: We should consider ourselves deeply indebted to Dr. Wenner for the comprehensive manner in which he has presented this paper on the management of foreign bodies of the cornea. Injuries of the cornea constitute the most common eye emergency that the general practitioner, as well as the ophthalmologist, is called upon to treat. They are as a rule attended by considerable discomfort and their sequelæ may result in considerable loss of vision if improperly treated.

It is not my intention to discuss the routine technical or statistical aspects of Dr. Wenner's paper, but rather to emphasize a few points in regard to the prevention and therapy of complications which may follow lesions due to foreign bodies of the cornea.

It should be remembered that many corneal lesions become infected by the pneumococcus group of organisms which are nearly always present in the lacrymal sac. It is advisable in all foreign body cases to be sure that the tear sac is free from low-grade inflammation, for a retrograde infection from this source is often of considerable virulence and difficult to treat.

Chemical cauterization of the damaged corneal area has been mentioned. The work of Gunderson on the iodine therapy of herpetic lesions of the cornea has conclusively demonstrated the effectiveness of iodine solution as an antiseptic in external infections of the eye.

The strong solution of iodine (U.S.P.) which contains seven per cent iodine and five per cent potassium iodide is extremely well tolerated by the cornea and conjunctiva if immediate neutralization with 4 per cent cocaine is carried out. The combination of iodine and cocaine results in the precipitation of insoluble cocaine iodide.

It has been our routine practice to apply the full strength iodine to all corneæ immediately after removal of foreign bodies, and then to flood the conjunctival sac with a solution of four per cent cocaine. The iodine is applied to the cornea by means of a finely pointed toothpick applicator wound with sterile cotton. This procedure is also employed in many cases of infected ulcer. No harmful effects have been noted and it is felt that the number of infections following trauma has been appreciably diminished. Tincture of iodine has the advantage of being readily available, and if nupercaine ointment is instilled in the conjunctival sac the patient experiences little or no discomfort.

In cases of frank infection it is often desirable to employ a stronger cauterizing agent. For this purpose trichloracetic acid is highly effective. After corneal anesthesia is established, the infected area is touched with a minimum amount of a freshly prepared aqueous solution of trichloracetic acid. Care must be exercised to avoid an excess of the chemical and the cauterization should be carefully confined to the infected area.

It has been noted that uninfected corneal abrasions tend to heal more rapidly when the intraocular tension is lower. To this end, if there be no threat of iritis, a 1 or 2 per cent solution of pilocarpine instilled in the conjunctival sac will bring about more rapid regeneration of the corneal epithelium.

If there is an associated iritis, foreign protein therapy with intravenous triple typhoid injections followed by paracentesis of the anterior chamber, the so-called interference therapy of Brown, will result in an increased concentration of antibodies in the aqueous with beneficial effect upon the inflammatory process. If an extensive ulcer results from trauma despite energetic local and general measures, so that perforation of cornea and panophthalmitis is threatened, a delimiting keratotomy may be considered. Another maneuver which may prove useful in deep uninfected wounds of the cornea is conjunctivoplasty, the cornea being covered by a sliding conjunctival flap to promote healing and prevent kerectasia.

CASE REPORT

TREATMENT OF HEMORRHAGIC RETINITIS WITH THE ANTI-HEMORRHAGIC VITAMIN: PRELIMINARY REPORT

EDWARD P. BURCH, M.D., and JOHN R. MEADE, M.D.

Saint Paul, Minnesota

THE initial report of an anti-hemorrhagic factor in the diet of chicks which protected them against hemorrhagic diatheses was made by Dam[1] in 1935. He termed this factor vitamin K. In 1937 Snell[2] reported the successful use of this substance in the control of hemorrhage in patients suffering from jaundice. His experience led us to believe that vitamin K might be of value in certain types of retinal hemorrhage.

In some cases of retinal hemorrhage none of the usual causes such as hypertension, arteriosclerosis, diabetes, nephritis, the blood dyscrasias, and tuberculous periphlebitis are found after exhaustive clinical and laboratory examinations. This group of unexplained hemorrhages constitutes the so-called idiopathic hemorrhagic retinitis which it was believed might be benefited by treatment with the hemorrhagic factor or factors contained in the fat-soluble substance termed vitamin K. It is our desire to place on record the report of a case of multiple retinal hemorrhages which apparently falls into the idiopathic group and which appears to have shown improvement under vitamin K therapy. The object in reporting the case is to stimulate interest in the treatment of retinal hemorrhages since the present methods of treatment seem deficient in many respects.

Case Report

Mr. A. E., fifty-one years of age, a railroad employe, was first seen on April 29, 1938. He stated that one year previously he had noted blurring of vision in the left eye, together with slight ocular pain. He consulted an oculist, who prescribed a change of lenses and advised removal of some infected teeth. The condition persisted although the glasses were subsequently changed in October, 1937. The vision continued to fail progressively in the left eye and the right eye became involved to a lesser degree in April, 1938.

On April 29, 1938, examination of the eyes revealed them to be normal externally with normal pupillary reactions and extraocular movements. The intraocular tension measured 17 mm. of Hg. in the right eye and 13 mm. of Hg. in the left eye. Without glasses vision was 20/50+2 in the right eye and 2/200 in the left eye. Lenses improved the visual acuity in the right eye to 20/25—2, but vision in the left eye could not be improved by lenses. Ophthalmoscopic examination of the right eye showed the nerve head to be of normal color with well defined neuro-retinal margins and normal physiological cupping. There was slight edema of the macular region and scattered throughout the fundus were a few grayish white areas, which were interpreted to be the relics of previous hemorrhages. A few superficial hemorrhages were noted in the right fundus at this time. The blood vessels appeared to be free from arteriosclerotic changes. In the right eye the disc was normal. The macular region was edematous and definitely elevated. There was a fresh superficial hemorrhage along the inferior temporal vein and also a few scattered hemorrhages throughout the fundus. There were also several grayish white areas similar to those seen in the right eye. The blood vessels showed no arteriosclerotic changes. Hospitalization for study and treatment was advised and on May 4, 1938, the patient entered the Miller Hospital, St. Paul, Minnesota.

On admission the temperature was 98.6, the pulse was 70 and the respirations were 18. The blood pressure was 156/90. The patient's family and past history revealed nothing of importance except that in November, 1937, three infected teeth had been extracted. The inventory by systems failed to elicit any points which had a bearing upon the patient's ocular difficulties. A physical examination was completely negative except for the eye findings, no foci of infection being found in the mouth, sinuses or tonsils.

The laboratory findings were as follows: Red blood cells 4,500,000; Hgb. 80 per cent; white blood cells 7,800. Differential formula: neutrophils 59%; lymphocytes 36%; basophils 1%; eosinophils 2%.

The blood smear showed the red blood cells to be normal in appearance.

The bleeding time was three minutes.

The coagulation time was four minutes.

Urinalysis showed the urine to be alkaline with a specific gravity of 1.019. There was no sugar or albumin present and the microscopic examination was essentially normal.

The Kolmer and Kahn tests were negative.

The Mantoux test was negative.

The excretion of P.S.P. was 60 per cent at the end of two hours.

The blood urea was 19 mgms. per cent.

The patient was put on a regime of calcium gluconate drams I t.i.d. during his stay in the hospital. During the brief period of hospitalization his eyes remained unchanged, and he was discharged on May 6, 1938, to be followed on the outside. Upon leaving the hospital he was advised to continue the calcium therapy and to take pilocarpine sweats at home under the direction of his family doctor.

He was next examined on May 14 and on this visit the fundi appeared unchanged.

On May 27 he was re-examined and the fundi showed no new changes. Vision in the left eye was recorded as ability to count fingers at 2 feet.

It was decided on June 29 to institute treatment with vitamin K and the patient was given a supply of the vitamin and instructed to take one teaspoonful three times a day.

On July 20 the hemorrhages appeared to be absorbing and there were no fresh hemorrhages.

On August 31 the fundi were examined and with the hemorrhages were found to be completely absorbed, with the exception of one small paramacular hemorrhage in the left eye which did not appear to be recent. There were scattered areas of hyaline degeneration throughout both fundi which had resulted from previous hemorrhages and there was moderate edema of the left macular region.

The patient was told to continue with the vitamin K therapy and to return in two months. He reported on November 8 and stated that vision in the left eye was improved. Examination with the binocular ophthalmoscope revealed a picture very similar to that described on the previous examination. The right fundus was free from hemorrhages. In the left eye there was a very small faint layer of preretinal blood inferior and temporal to the left macula. There were numerous, scattered, grayish white hyaline-appearing areas in each fundus but no pigment disturbance. Vision with glasses was recorded as 20/30 in the right eye and 14/200 in the left eye.

Comment

Although one is never warranted in drawing conclusions from a single case, it is felt that the patient may possibly have been benefited by the administration of vitamin K. When first seen there was ophthalmoscopic evidence to indicate that in addition to the retinal hemorrhages of recent origin the patient must have at some previous date been subject to bleeding into the superficial layers of the retina. Careful clinical and laboratory examination did not elicit any of the usual causes for the hemorrhagic diathesis. On a regime of calcium therapy, the retinal picture remained essentially unchanged. The improvement which attended the administration of vitamin K was both prompt and striking, and over a five-month period no new hemorrhages have made their appearance. The dosage of 5 c.c. three times a day of vitamin K was purely empirical and further investigation may show that this is neither the optimal nor most efficient dosage to prevent hemorrhages. The authors, actuated by the striking results in this single case, have attempted to treat the hemorrhages of diabetic retinitis along similar lines. To date the few cases which have received this form of treatment appear to have derived little or no benefit from vitamin K therapy. All of the patients so treated were elderly diabetics and all showed marked vascular change in the retinal vessels.

It is hoped that by instituting treatment at an earlier stage in younger individuals whose retinal arterioles are free from organic change that some of the untoward results of retinal hemorrhage may be obviated.

In conclusion, the authors desire to express their appreciation to Mr. James Moore of the Archer-Daniels-Midland Corporation, who made it possible for them to obtain the vitamin K. This particular preparation is an oil extract of hemp which has been tested on chicks for its content of antihemorrhagic factor.

ALCOHOL IN RELATION TO TRAFFIC ACCIDENTS

Richard L. Holcomb, Evanston, Ill. (*Journal A.M.A.*, Sept. 17, 1938), reports the results of a study of the drinking of drivers involved in personal injury accidents and of the drinking of drivers in the general population. The second study served as a control of the first, allowing conclusions to be drawn as to the part alcohol plays in accidents. A total of 270 persons were tested in the first study. Drivers involved in personal injury accidents who accompanied the persons injured to a hospital or drivers who themselves were injured were tested by urinalysis for alcohol. A total of 1,750 persons were tested in the second study. Drivers were chosen at random from an area comparable to that of the first study. A complete testing laboratory, with the Harger "drunkometer," was set up in a trailer, allowing breath tests for alcohol to be made immediately. 1. The highest percentage of drinking drivers occurs in the early morning hours and over the week-end. 2. The largest number of drinking drivers occurs in the early evening and over the week-end. 3. The peak age for drinking drivers is from 25 to 30. 4. Women drink and drive as much as men when the number of women driving at various hours of the day is considered. 5. The percentage of drinking drivers in the general population varies as does the percentage of drinking drivers in the personal injury accident group but falls considerably lower at all times. 6. The percentage or number of drivers involved in personal injury accidents varies as does the percentage or number of drinking drivers. 7. As the blood alcohol content increases, the number of drivers appearing in the personay injury accident group increases out of all proportion over that in the general driving population. 8. As alcohol increases, accidents increase and at a rate somewhat proportionate to the increase in alcohol. 9. Equal percentages of drinking drivers are found in the accident group and in the general population group at a point near 0.5 part of alcohol per thousand parts of blood, indicating that alcohol in that amount is not necessarily a significant cause of accidents. 10. The data gathered in this study confirms a self-evident fact, that alcohol is a major cause of automobile accidents.

George A. Earl, M.D., *President*
Minnesota State Medical Association

President's Letter

The year 1939 is before us.

We start out, as a medical association, from a splendid vantage point. We have a fine heritage and our scientific standing is unquestioned. This applies not only to our famous personalities, but to the average level of our practitioners. From the standpoint of laws to protect the public health none are more fortunate than we.

We can do no better in the future than to follow the examples of the past. Thus we must stress, first, our mission as practitioners of medicine. We must show that our primary interest is scientific attainment and that we cherish, above all, our close personal patient-doctor relationship together with free choice of physician except for certain unavoidable and natural limitations, and hope to continue it.

Keeping in mind, then, our primary interest as practitioners we are going to begin this year a trial of what has come to be known as the "Indiana Plan." This trial was suggested by our retiring past president, Dr. Adson, and endorsed by my predecessor, Dr. Hayes, and by the Council. According to this plan, one topic, or related group of topics, is to be stressed each month in our public health relations. Dr. O'Brien will discuss it over the radio, it will be emphasized in our regular press releases and in public talks before lay groups.

The subject is to be of seasonal interest if possible, with Pneumonia selected for this first month of January. Coöperation of MINNESOTA MEDICINE and of our societies and membership in general has been enlisted in carrying out this plan. Insofar as it does not interfere with previously arranged programs, county societies will be asked to include a paper on the subject at their regular meetings.

In addition to our scientific pursuits and related public health contacts, we are obliged, these days, to give our attention to Socialized Medicine, so-called. Probably the term "Government Medicine" is more exact since in the minds of many people "Socialized Medicine" refers also to voluntary efforts along insurance lines and not under government control.

The question of Government Medicine is undoubtedly in the foreground of public consciousness. Scarcely a lay magazine feels its pages are complete without an article on it. It is for this reason that an Institute on Socialized Medicine has been proposed. The objective of this institute would be to provide our members with a general review of the effects of government in the care of the sick, both as we know it in this country and as it has been observed in Europe. Besides this presentation of facts, we hope to have an analysis of methods of presentation.

We are happy to announce that we have secured Mr. J. G. Crownhart, Executive Secretary of the State Medical Society of Wisconsin, to give us the facts about government medicine in Europe. Those of us who heard Mr. Crownhart give an address in Duluth recently can vouch for it that his talk alone will be worth the trip to the Institute. Dr. W. A. O'Brien and others will participate in discussions. Every member is invited to attend. The date and place is January 14, 2:30 p. m. at the Saint Paul Hotel Ballroom, Saint Paul, Minnesota.

GEORGE EARL, M.D., *President*
Minnesota State Medical Association.

HISTORY OF MEDICINE IN RAMSEY COUNTY

BY J. M. ARMSTRONG, M.D.

(Continued from December issue)

1854

In the library of the Minnesota State Historical Society is a small octavo pamphlet of eight pages called the *Minnesota Homeopath,* Vol. I, No. 4, January, 1859, published by George Hadfield. It, no doubt, was our first medical journal, if it can so be considered. It contains an article on homeopathy, testimonials, and advertisements of Dr. Hadfield's medicines. No other copy appears to be known and no reference to it is to be found in the Index Catalogue of the Surgeon General's Library. Hadfield's office at that time was on Fourth Street just below the Seven Corners where the Arlington Hotel now is. He left, it is said, about 1860 for Memphis, went thence to Little Rock and after the war to Chicago. In 1869, he settled in Cincinnati and exploited a machine for equalizing the circulation of the blood. No further history of him has come to the notice of the writer. He was a man of no culture and a poor physician.

Three physicians not previously mentioned came to St. Paul in 1854 and remained but a short time, Dr. W. W. Mayo, later of Rochester, Dr. Percival Barton, and Dr. John Lambert, of Saco, Maine. Possibly, the latter did not come till the following year. He was still in St. Paul in September, 1855, as an infant daughter of his died there on September 5, 1855. Dr. Barton remained but a short time and then moved to a farm at Inver Grove, Dakota County. More will be heard of him later. On February 2, 1854, Dr. L. C. Kinney received from the county commissioners the sum of one hundred dollars for the care of some smallpox patients. In the fall, Dr. Frederick Andros moved down from Long Prairie, having been elected to the Legislature. He left for Iowa after the legislative session the following spring.

1855

The year 1855 in St. Paul was an eventful one as far as the medical profession was concerned, as some of the men who later became prominent in the profession arrived during that year. There were some changes in the drug business: Dr. Kinney sold his store to Dr. Morton and Thomas E. Pace, the latter having been Dr. Kinney's clerk. Kinney opened a livery stable, and Wolf and Steever opened the Central Drug Store on Third and Wabasha Streets.

The papers for June 26 state that St. Joseph's Hospital had been opened but a short time, and that ten persons were being cared for there, none of whom was a charity patient. The Christ Church Orphans Home and Hospital was incorporated in March. This organization became the nucleus of what was later to be St. Luke's Hospital. The building it occupied still stands at Nos. 87 and 89 Park Place. On account of the muddy roads in the spring the stage coach overturned while conveying passengers between St. Paul and St. Anthony, and a

Mr. Scott and a Mr. Hoyt of St. Paul were injured. Scott suffered a broken leg and Hoyt's head was cut. They were cared for by Dr. Murphy. At the meeting of the county commissioners on April 16, Dr. Goodrich was allowed a quarter salarly of $200 as health officer, and A. M. Fridly, the sheriff, presented a bill for $500 for boarding, and hanging the Indian Utrazy (variously spelled) who had committed a murder in the city. Dr. Willey presented a bill for $50 for medical services rendered to the same Indian. After due consideration the county commissioners cut the sheriff's bill to $225, and allowed Dr. Willey $30. Inasmuch as the latter's services were pronouncing the man dead, after the sheriff had hanged him, the amount was deemed sufficient. According to eye witnesses of this hanging it was quite a gala event. No gallows were erected and the public, if not invited, was present in large numbers. The man was hanged to the limb of an oak tree that grew where the St. Paul Catholic Orphan Asylum now stands (933 Carroll Avenue), at that time quite a long way from town. Shortly after this event, Willey was appointed city physician by the Board of Health, and Dr. David Day returned from Philadelphia, where he had gone to receive his diploma from the University of Pennsylvania.

There was considerable guarded news about cholera in the papers during the summer, and editorials appeared denying that any St. Paul residents had suffered from the disease. Six new physicians came to St. Paul this year. Franklin R. Smith, whose card appeared in the paper under date of November 21, occupied the residence which had recently been vacated by Dr. Biddle. He gave Ex-Governor Ramsey and Hon. David Cooper as references. On December 1 the cards of Drs. John V. Wren and Jacob Henry Stewart appeared in the papers, together with the announcement of St. Paul's first out-and-out medical quack, Russell Post. Notices of these men appear elsewhere in this sketch. The year 1855 also saw the arrival of Drs. J. C. Merrill, Gustavus Rosenk, John B. Phillips, Rudolph Alberti, and James Dorsey. Dr. A. P. Marsh, who at one time had his office with Dr. Goodrich, and played a small part in the organization of the Minnesota Medical Society, moved from St. Paul, probably to Philadelphia. It was surmised by some that his diploma was stolen or forged. Merrill was a homeopath who later called himself Professor Merrill. He played no part in our medical history. He died in St. Paul. The late Dr. Merrill of Stillwater was his son. Alberti, who was somewhat of a mystery, was either a German Jew or a Pole. Berthier was a French Canadian who remained some years and then went to France or Canada. Alberti, Berthier, and Rosenk were not considered by the regular profession to be reputable practitioners. However, they are of sufficient interest to warrant a brief mention of them. As to Dorsey, no more appears to be known than that he came to St. Paul and inserted his card in the paper. A Dr. James Dorsey received the M.D. degree from the University of Maryland in 1825. Whether or not he is the same man is not known. He probably moved on to a better location. Dr. Phillips was a man of education and culture, but he practiced little or not at all in St. Paul. Most of the other men, with the exception of Rosenk and Post, lived only a short time in the city. The two last named remained for a number of years. Their announcements, therefore, may be quoted in full.

Dr. Post

> Pearl Street, South Side, 2nd door west, Baldwin School, St. Paul, would offer his professional services to the public, for the cure of all Chronic Diseases. Examinations made and full descriptions given without previous knowledge of the case or asking any questions.
>
> Practice—Electric and Electro-Magnetism

Dr. G. Rosenk

German Practical Physician

> Formerly teacher at the Midwife Academy and District's Physician recommends himself in Surgery, Midwifery, and Dentistry and will cure all external and internal diseases of male as well as female persons so as to let them have a cheaper medical attendance, and will do midwifery to poor women without charge.

1856

Late in the year the first published directory in book form for St. Paul appeared. The classified list of physicians together with the location of their offices is as follows:

Alberti, R., St. Anthony St., corner of Wabashaw.
Berthier, Alfred, Seventh St., near Rosabel.
Bunting, J. C., St. Anthony St., Opp. Presbyterian Church.
Dewey, J. J., St. Paul St., below Somerset.
Goodrich, J. D., Third St., below Robert; house, Fifth St., between Jackson and Robert.
Hadfield, George, Third above Minnesota.
Merrill, J. C., St. Anthony St., above Presbyterian Church.
Miller, W. H. (German), St. Anthony St.
Morton, W. H., Third St., near Robert.
Patterson, M.D., Phoenix Block near Post Office.
Potts, T. R., Robert St. between Fifth and Sixth.
Rosenk, Gustavus, St. Anthony St. near Hill.
Smith, F. R., Main St. near Market.
Stewart, J. H., Phoenix Block near Post Office.
Steele, John, Tenth cor. Cooper.
Wren, J. V., Fort near Snelling House.
Veiden, T. J., Third between Robert and Minnesota.
Willey, Samuel, St. Anthony below American House.

Dr. Brisbine's name appears in the body of the directory but was left out of the classified list. The omission may perhaps be explained by the fact that Brisbine was abroad during the year. It will be seen that the list numbers eighteen names. Kellogg Boulevard above Wabasha was then called St. Anthony Street. Olive Street was then St. Paul Street. Fourth Street above Wabasha was then called Main. The Post Office was on Third Street between Washington and Market, and the Presbyterian Church, on Third and St. Peter, stood on the site now occupied by the Women's City Club. The Phoenix Block was on Third Street near Washington on the south side. West Seventh was then known as Fort Street.

Five new names of physicians appear on this list: Drs. Bunting, Patterson, Steele, Smith and Wren. Bunting came from Philadelphia. He was a brother-in-law of Wolff, the druggist, and died of tuberculosis. Wren was in St. Paul several years. He had been a preacher, it is said, before he was a physician, and he paid more attention to politics than to medicine. He was city physician in 1857-1858 and coroner in 1858-60. During the years 1862-1864 he served in the army and was stationed at Fort Ripley. His portrait may be seen with that of the other city officials of 1857-1858, in the County Auditor's office in the Court House. Patterson was an M.B. by baptism and a dentist by profession. John Steele arrived in the summer of 1855 from Strasburg, Pennsylvania. He was a brother of Franklin Steele and practiced in St. Paul for twenty-eight years before retiring. He died in 1885. Like many of our early physicians he came because of his health. Dr. John Steele Abbott is his grandson. Dr. John A. Vervais also came to St. Paul this same year. Other than being mentioned as on the staff of St. Joseph's Hospital in 1859 and as city physician, he does not appear to have been very active in a medical way. For the most part the French Canadians kept to themselves and mixed but little with the rest of the population. The biographies of Franklin R. Smith and of a Dr. W. S. Cox who came to St. Paul this year will appear later.

Two other medical men not previously mentioned who were destined to play a prominent part in the future history of medicine in Minnesota, came to St. Paul in 1856. They were classmates at the University of Pennsylvania and arrived on the same steamboat. Both passed the remainder of their lives in St. Paul, and both became president of the Ramsey County Medical Society. They were Drs. Alfred Wharton and Daniel W. Hand. Wharton was a tall aristocratic man, correct in dress, manners, and deportment, quick of perception, very able professionally. Hand was shorter, rather a plodder, and a hard worker. He was interested wholly in his profession and anxious to keep in touch with every new development in the science of medicine. Wharton had money, while Hand had none. Wharton made money both in his profession and out of it. Hand finally accumulated money in his profession but worked very hard for it. Hand did everything that was thrust upon him which was for the good of the profession or for the public. He gave much of his time to teaching, to serving as a member of the State Board of Health and the State Board of Medical Examiners, and to other duties which brought him little, if any, financial return. Wharton shirked no responsibility but sought none. He retired from practice in 1885, living until 1920 and looking twenty years younger than his age until shortly before his death. Hand aged rapidly, became very deaf, and practiced till the last.

Dr. Wharton related to the writer the following incident which occurred one Sunday afternoon shortly after the two men arrived in St. Paul. They went for a walk toward the outskirts of the city, and Hand remarked that he wished he had brought along a skull from Pennsylvania. He had not been able to find room for one in his baggage. After walking for a time they reached a spot near the present corner of College Avenue and St. Peter Street, then the northern boundary of the city. There was a spring there, and that with a heavy rain had washed out a gully in the side of the hill and exposed a coffin. They went back after dark and Hand got the skull. In later times when the houses on the east side of St. Peter Street were built, other coffins were found. This was the site of the Catholic Cemetery from 1849 to 1854 (bounded by Summit, Wabasha, College, and St. Peter). Previous to this time the cemetery was on Bench Street north of the old log chapel of St. Paul from which the city takes its name. Skeletons were dug up on this latter site also in later times when the Stees block and the present *Dispatch-Pioneer Press* building were erected. When the present Federal Farm Loan Bank building was built (about 1911) a skeleton was unearthed under the sidewalk on the north side of Fourth Street. The workmen left it there. The present Calvary Cemetery was preceded by another one on the site now occupied by St. Joseph's Academy and northward. When the writer was a boy, he saw some skeletons unearthed during the installation of either sewer or water pipes on Iglehart Street between Farrington and Western Avenues. In the autumn of 1930 when an addition was being built to the Academy building, some coffins were unearthed during the excavation for the foundation.

Another medical man came to St. Paul during this year, who, though he never practiced medicine, was a man of charming manners and was well known to the early settlers. He had practiced or attempted to practice in Chicago, but became associated upon his arrival here with the Zimmerman photographic galleries and made his living painting miniatures, one of which, to the writer's knowledge, is very well done. He died in St. Paul about 1882. He was a graduate of the University of Copenhagen in 1850. A pair of obstetrical forceps in a buckskin bag and some woolen obstetrical tape which belonged to him, also some of his manuscript lecture notes, are in the museum of the Ramsey County Medical Society. The forceps are, without doubt, one of the most beautiful examples of polished, hand forged steel ever seen. His name was A. Falkinschield.

1857

This was the year of the financial panic. For three years there had been an unbridled speculation in real estate, and land had been in such a demand that investors, buying and selling on a rising market, were able to make a profit, even though they must borrow money at three per cent or more per month. Every boat coming up the river brought in scores of immigrants, speculators, and many others looking for easy money. St. Paul was known as the liveliest and toughest town on the river, a place where thefts and even murders were common.

In 1857, the bubble burst. Hard money disappeared and currency issued by banks became worthless, since its value was based upon speculative land values. Even money issued by the county, the city, and the state, was valued at only forty cents on the dollar. The entire population was affected. To keep people from starvation, the city projected public improvements, paying for the labor in scrip. In the meantime a vigilance committee was organized, and the rowdy element was forced to leave town. Notwithstanding these hard times, three new physicians came to town. The card of Dr. H. Wedelstaedt, homeopathist, appeared in the *Pioneer* and *Democrat* on November 15. He gave Dr. Hadfield and Dr. Pulto of Cincinnati as references. He remained in St. Paul the rest of his life and was very well known there. Dr. Sylvester J. Sawyer inserted his card in the paper of October 15. He stated that he was "late Surgeon to Bellview Hospital, New York City." He left a year or so before the Civil war. While in St. Paul he married Helen Hastings, halfbreed daughter of one of the early settlers. Dr. J. H. Studdeford's card appeared in the paper on October 16. He claimed to be late house surgeon to the Blackwell's Island Hospital, New York. Apparently he remained but a few months as no other information about him is available. In April, 1857, Samuel Medary arrived. He had been appointed Territorial Governor of Minnesota. With him as his secretary came Dr. Thomas Edwin Massey of Columbus, Ohio.

Massey had formerly been a resident of Hot Springs, Virginia, and had graduated from the University of Pennsylvania in 1846. For some years prior to his arrival in Minnesota he divided his attention between medicine and journalism, and became the editor of the *Ohio Statesman*. An article written by him on the subject of the inflammation of the female genital organs was published in the first number of the *Ohio Medical and Surgical Journal* (September, 1848). During his period of residence in St. Paul his practice of medicine was subordinated to other interests. In January, 1862, he started a newspaper called the *St. Paul Journal* (weekly), but the paper did not flourish, due to the fact that its political affiliations were with the anti-war Democrats, and publication was suspended at the end of eight months. Dr. Massey presented an early form of stethoscope to Dr. C. E. Smith, Sr. It closely approaches in design the original wooden stethoscope pictured in the second edition of Laennec. Massey lived in St. Paul until about 1863, when he returned to Ohio. Of his later activities little is known. He moved during the following decade to Colorado, where he probably continued his interest in journalism and in medicine. In 1874, he published in Denver a small pamphlet entitled the "Relations of Colorado to Pulmonary Consumption." The following year an article by him appeared in the Transactions of the Colorado Territorial Medical Society. The paper was one which he had read before the society in 1873. It is stated that he went from Colorado to Washington (state?).

(To be continued in February issue.)

EXTENSION OF GOVERNMENT MEDICAL ACTIVITIES

THE present Congress is doubtless going to be called upon to appropriate huge sums for increasing government health activities on a national scale. Although the Interdepartmental Committee in its report last July favored compulsory sickness insurance as a government activity but did not recommend it at the time presumably on account of the billions of dollars involved, the committee did approve legislation to extend in various ways government health activities, which it is estimated will amount to 485 million dollars a year.

The medical profession as a whole sees no need for expenditures on such a scale, and its members as citizens and taxpayers know that the federal government with an annual deficit of several billions of dollars could not afford such appropriations if they were needed. This attitude may seem inconceivable to the theorists who are directing government activities in Washington with a total disregard for adjusting expenditures and income.

If the medical profession of this country is convinced that the extension of government in medical activities leading more and more towards state medicine resembling that established in Europe is undesirable, it should take a militant stand on these proposals as they appear in Congress by letting representatives know, in no uncertain terms, its convictions.

And, if any physician has no convictions as to the comparative values of medical care as furnished by so-called private practice as typified by medical practice in this country, and medical care as furnished by government sickness insurance in Europe, let him read the report* by the secretary of the Wisconsin State Medical Association of the operation of state medicine in England, France, Germany, Denmark, Norway, and Sweden.

A student of social problems, and particularly those associated with medical practice, Crownhart was well prepared to undertake this investigation. Convinced that conflicting reports of the operation of sickness insurance in Europe can be explained on the basis of restricted viewpoint, Crownhart studied the systems in the countries mentioned from the standpoint of the insurance administrators, the labor organizations, the farmers, the hospitals, the physicians and the insured individuals. The picture he paints is of a medical service falling far short of the goal aimed at by the proponents of socialized medicine, limited in its social service by inadequate insurance funds and necessitating a huge administrative personnel. Inseparably associated with compensation for loss of wages, the sums involved are enormous.

---

*Crownhart, J. G.: Sickness insurance in Europe. Price, $1.00. State Medical Society of Wisconsin, Madison, Wisconsin.

The question of the enactment of legislation approaching state medicine is a live one. Proponents of change in medical practice are most energetic. The article entitled "A.M.A." in the November *Fortune* was doubtless written largely in a provocative mood. The one entitled "Rehearsal for State Medicine" in the *Saturday Evening Post* for December 17 is an illustration of how medical practice can be changed by a governmental agency when someone in authority thinks there is need.

What should the attitude of the medical profession be? Certainly we should voice our conviction that panel system medicine is inferior medical care. The emergency care provided for 77,000 Farm Security Administration clients in North and South Dakota and elsewhere may be necessary to maintain medical care in localities unable to support doctors, but such a system is supported by taxpayers elsewhere and is not therefore generally applicable.

It must be remembered that proposals to apply a changed system of medicine to those with an income of $1,500 a year or less, is going to affect 90 per cent of the population and those with $3,000 a year or less some 97 per cent.

As Crownhart concludes, each state must study its own medical needs and decide whether the sickness insurance in Europe which falls far short of ideal medical care, is wanted.

The real need for financial assistance in meeting the cost of sickness is not for the payment of an occasional visit from the general practitioner. Although the total of this item is a large sum it is so widely spread that it does not present a hardship to the individual patient. The item that requires the financial assistance readily furnished by insurance, is the cost of an acute illness requiring in most instances hospital care and services of specialists and nurses or of a prolonged illness involving loss of income. The hospital associations are meeting part of this liability by insurance methods and there is reason to believe that cash indemnity or similar policies issued by commercial insurance companies or by non-profit mutual organizations, can meet such a need on a much larger scale than they do at present. We shall watch with interest the working out of experiments along this line recently inaugurated in California and Wisconsin. The response of the public to insurance against hospital bills, suggests the likelihood of a similar reception of insurance against other costs incidental to hospitalization.

It is difficult for the average layman to grasp the facts here brought out. It would be well for members of the profession to explain to their patients that it is to the advantage of public and profession to avoid extension of medical service supplied by government agencies. Our representatives in Washington wish to know what their constituents think on the subject.

THE MEGAKARYOCYTE

SYMMERS[5] has recently reiterated a statement he articled first in 1917,[6] bearing upon the relationship of Hodgkins' disease with the megakaryocytes of the bone marrow. W. B. Castle[1] lecturing before the Victorian Branch of the British Medical Society in Australia is reported in the letter to the A.M.A. as stating "Hodgkins disease is a megakaryocyte Tumor."

This is a challenging statement. Medlar[3] appears to have had the same concept and called Hodgkins a metastasizing tumor—a "megakaryocytoblastoma." Bunting and Minot both discovered megakaryocytes in the small blood vessels of lymph glands in patients with Hodgkins disease. This is a field in which opinions have arisen chiefly through cytological study and morphological resemblance. All observers must agree that they are looking at cells more or less distorted in processing and staining. At the same time the method has been highly productive and has greatly advanced knowledge. Nevertheless the megakaryocyte (and their exclusive marrow origin seems to be accepted) has not been as easy to study as early erythropoietic or leukopoietic forms.

We should recall that the thrombocyte is a sticky blood traveler and it is his business to agglomerate where exposures occur and barriers are broken—hence the "white clot." The parent megakaryocytes are likewise subject to easy distortion. Liniarzi[2] and his associates at the University of Illinois have recently offered a technic to obviate some of this distortion. The needled sternal marrow is handled in paraffine lined tubes and pipettes and centrifuged at high speed to send the adult red cells to the bottom of the Wintrobe tube and leave the serum and early leukocyte and platelet precursors juxtaposed in the midportion. From a mixture of these, smears are made of surpassing excellence. Ponderous systems on hematology have not given much satisfaction to the clinician already weighed down by the burden of voluminous terminology and endless repetition. Neither do we profit especially by reference to encyclopedic summaries that aim to leave out mention of no one in any land who ever ventured to express an opinion or submit an observation.

It is necessary to have accurate data concerning the thrombocytes in all essential and secondary depression of the megakaryocyte sequence. Otherwise, splenectomy will be ventured where entirely contraindicated as, for example, in toxic purpura, concealed poisoning, or even in aleukemic leukosis. Rhoads and Miller[4] have recently published data on four different groups of marrow in so-called "aplastic anemia." All were anemic but the marrow varied from true aplasia through grades of hyperplasia with retention of marrow products, and group 4 which is a megakaryocytic replacement of other elements and is comparable to the anemia of the leukoses. Hodgkins continues to be a great puzzle; but whether megakaryocyte studies shall help to advance its therapy or not, there is a wealth of clinical interest centered in the factor of physiologic repression exerted upon the bone marrow by the spleen. This is best exemplified in essential thrombocytopenia where splenectomy cures.

Limarzo's technic promises to give diagnostic assurance in this field as well as in the dubious and uncertain "aplastics" where diagnoses are beset with many pitfalls and uncertainties.

PNEUMONIA IN MINNESOTA

THE selection of pneumonia as the subject for emphasis in the month of January is particularly timely, for it is in the winter months that pneumonia is most prevalent in Minnesota. Although pneumonia in Minnesota is not as prevalent nor as serious a disease as in certain other states, we do lose from 1,600 to 2,600 citizens yearly from pneumonia of all forms. We have probably three or four times as many cases as this in the state each year and this winter promises to have an increase over recent years.

About half the reported deaths from pneumonia are lobar in type. Inasmuch as it has come to be more generally recognized that an appreciable percentage of broncho-pneumonia is caused by the pneumococcus, several thousand individuals in the state each year are potential candidates for pneumonia serum.

Minnesota has joined several of the eastern states, notably New York and Massachusetts, in a campaign to fight pneumonia. Two years ago facilities were first offered by the State Board of Health for typing the pneumococci and limited amounts of anti-pneumococcic serum for Types I and II were made available to those unable to afford this valuable adjunct in the treatment of the disease.

The value of specific serum in the treatment of the corresponding types of pneumococcic pneumonia having been well established, it behooves every physician likely to be called to see a patient suffering from this disease to be prepared to take advantage of the oppoutunities for typing and the procuring of free serum, if the patient cannot afford it.

If a sputum outfit put out by the State Board of Health is not available, a small but wide necked bottle may be used to collect the sputum, which must be that coughed up from the bronchial tubes and should be at least 5 c.c. in amount. In the case of children, when sputum so often cannot be raised, the child should be placed with the affected side up and induced to cough by tickling the pharynx with a sterile swab from a diphtheria culture outfit and the raised sputum colected from the throat by means of the swab. In order to keep the swab moist during transit, the swab is then pushed into the medium in the diptheria culture tube, not simply rubbed on the surface of the medium.

The sputum specimen is then mailed or sent (whichever is quicker) to:

Main Laboratories, Division of Preventable Diseases,
University Campus, Minneapolis, Minnesota
Duluth and St. Louis County Branch Laboratory
228 New Jersey Building, Duluth, Minnesota
Rural Health District No. 1
City Hall, Bemidji, Minnesota
Rural Health District No. 2
Court House, Mankato, Minnesota
Rural Health District No. 3
City Hall, Rochester, Minnesota

A telephonic or telegraphic report will be sent by the laboratory as soon as possible if typing is successful and therapeutic serum is available, or if time permits the submission of another specimen.

The various laboratories may be reached after hours or on Sundays and holidays as follows:

Main Laboratories, University Campus—Call University of Minnesota telephone operator and ask for Pneumonia Typing Service.
Branch Laboratory, Duluth—Call Hemlock 907 or Hemlock 5040-W.
Health District No. 1, Bemidji—Call District Health Officer.
Health District No. 2, Mankato—Call District Health Officer.
Health District No. 3, Rochester—Call District Health Officer.

Although the funds available for the purchase of serum are limited, as long as it lasts type sera other than types I and II will be furnished direct from the Main Laboratories, Division of Preventable Diseases, State Department of Health, University Campus, Minneapolis, as follows: III, IV, V, VI, VII, VIII, XII, XIV, XVII, XVIII, XIX, XXVIII and XXIX. In addition type sera XIII, XV and XVI will be secured air mail by Main Laboratories when typing is carried out early enough to obtain the serum in time for use. Serum thus ordered should reach Minneapolis inside of twenty-four hours.

It is generally conceded that after four days have elapsed from the onset of symptoms of pneumonia, serum is not likely to be of benefit. Fast action is therefore essential.

As valuable articles on the subject of pneumonia in Minnesota, we recommend those by Drs. Heathman, McDaniel and Chesley which appeared in this journal for January and December, 1937. An authoritative booklet on serum treatment is one entitled "Pneumonia and Serum Therapy" by Frederick T. Lord and Roderick Heffron, published by the Commonwealth Fund, New York.

In Memoriam

Gustave Adolph Christensen

1864-1938

Dr. Gustave Adolph Christensen, a pioneer physician at Cass Lake, died at his home October 9, 1938, at the age of seventy-four. He had practiced in Cass Lake since 1901 when he left Granite Falls.

Dr. Christensen was born in Chicago on March 2, 1864, the son of Rev. Emil and Amelia Christensen, pioneer missionaries who established the first Lutheran mission post in Oregon. He was sent to boarding school and received his medical education in Indianapolis, Indiana. In 1888 he was married to Delia Thykeson of Albert Lea, Minnesota, and from this union seven children were born, five of whom survive.

Records fail to show what medical school was attended by Dr. Christensen. He was never a member of the Minnesota State Medical Association.

Frederick A. Stevens

1860-1938

Dr. Frederick A. Stevens, a resident of Lake Elmo for more than fifty years, died during the night of November 28, 1938, at the age of seventy-eight.

Frederick Stevens was born October 28, 1860, at Mantorville, Minnesota, the son of Edwin A. Stevens who was at one time a member of the editorial staff of the *Pioneer Press,* Saint Paul. Dr. Stevens graduated from the Central High school in Saint Paul. After finishing sophomore year at the University of Minnesota, he graduated from the Hahnemann Medical College, Chicago, in 1883, and the same year was licensed in Minnesota.

After spending two years doing postgraduate work at the New York Ophthalmic Institute, the College of Physicians and at the Bellevue Hospital, Dr. Stevens located at Lake Elmo in 1887. His early surgical work was done in homes in or close to Lake Elmo until the Lake Elmo Sanatorium was built. When this proved too small, he transferred his patients to Bethesda Hospital in Saint Paul.

Dr. Stevens joined the Ramsey County Medical Society September 29, 1913, and was a member of the Minnesota State and American Medical Associations. He was married January 14, 1914, to Gertrude Londigan, who with their daughters, Kathryn, Gertrude and Marian, survive.

Dr. Stevens was a hard worker, a genial companion, a generous entertainer and had the faculty of endearing himself to his patients who always became and stayed his friends.

He will be greatly missed in the community where he lived and worked so long and for which he did so much.

E. Sydney Boleyn.

MEDICAL ECONOMICS

Edited by the Committee on Medical Economics
of the
Minnesota State Medical Association
W. F. Braasch, M.D., Chairman

REHEARSAL IN MINNESOTA

In the wake of the widely read *Saturday Evening Post* article entitled "Rehearsal for State Medicine," four officials of the Farm Security Administration presented themselves before the Council of the Minnesota State Medical Association, December 15, in Saint Paul.

These officials confirmed the astonishing extent of various types of medical services for Farm Security Clients described in the article—declared that in each case the plan employed had been worked out by the local county or state medical society—asked the Council to work out some similar plan for care of the farm families of Minnesota who are now receiving loans from the Farm Security Administration.

Problems of Lower Third

Said Spokesman Dr. H. V. Meriwether, United States Public Health Service:

Many farm families in the lower third of farm brackets are in need of medical and dental care.

The Federal Farm Security Administration is trying to rehabilitate these families by loans and by consultation to revise their farming methods and living habits so that they will be able to make a living on their farms and also payments on their loans.

About 80 per cent of these families are making their payments as scheduled. Where they fail we find medical and dental problems in every case. Clearly we cannot continue our program successfully without provision for medical service for these farmers and we have come here today to ask the Minnesota State Medical Association to devise a plan for caring for our families in Minnesota.

Plans Vary

Already there are thirty-two different plans in operation in thirty-two different states. The plans vary because the medical societies, in each case, dictated the plans. In general, there are two different types of arrangement—individual arrangements and "pool," "insurance" or "cash indemnity" plans.

In Ohio, with the individual plan, the list of doctors who wish to participate goes to the farm clients. The client selects his doctor and he and the doctor get together to decide what the client will need for the year. The Farm Security Administration provides the funds.

In Logan County, Ohio, all of the money is put in the hands of the Logan County Medical Society. The custodian of funds for the society pays the doctors' fees according to a prearranged schedule until the money runs out. From then on it is between doctor and patient. The doctor must continue in attendance until the end of the year, however, no matter how the funds hold out.

72 Per Cent of Normal Fees

In the "pool" or common fund plan, the farm client pays a definite sum each year. In the South it is usually $12; in the Northwest $20 to $30. Each client is issued a card with a number and he may call anybody in the medical society to take care of him. The doctor submits his normal fee at the end of the month. If there is enough money to warrant it he is paid 100 per cent of his bill. If not, the amount paid is pro-rated down to whatever the fund can pay. On the average, about 72 per cent of normal fees have been paid in all counties to date. If any money remains after fees are paid, it is held to the end of the year and pro-rated, then, to the doctors.

In County Society Hands

In several counties in Iowa the doctor submits to the county society only an account of services; the county society sets the amount. In any case, the entire matter remains within the county medical society.

And I personally believe that all of these matters should remain in county medical society hands.

Rehabilitating Doctors

North and South Dakota have presented a separate problem. The doctors, as well as the patients, needed rehabilitation if the doctors were to remain in practice there.

The plan in operation was suggested by the doctors. It has been changed three times and the money appropriated has been increased three times.

Last year 92 per cent of the medical bills were paid on a 66 per cent basis for the 67,000 relief load. The question is: shall we shift to a loan instead of a relief basis? Already some 8,000 families are on a loan basis and gradually we may shift entirely to the loan set-up. Payment of medical bills will continue to be on a 66 per cent basis.

The doctors themselves believe they are going to work out something in Dakota that may ultimately be of benefit to all medical societies.

Hospitalization Also

We are working in Dakota toward a group hospitalization plan to take care of all low income families. In Logan county, also, we are making arrangements to take care of hospitalization for our clients on a group hospitalization plan.

We have found in some communities that as many as 38 per cent of adults need restoration of teeth. We are working with the dental societies now, to see how this type of dental work can be done.

For young people we try to provide glasses. For older people we are willing to relinquish a portion of the milk income to permit them to buy glasses.

8,000 in Minnesota

In Minnesota we ask that the state medical association work out the broad plan for care of our Minnesota clients. The county societies can work out the details. There are approximately 8,000 farm families receiving loans from the administration now in this state. About 75 per cent of these families are in the northern part of the state, about 25 per cent in the South. In the North and the West there are from 125 to 150 families in a county. A local superintendent makes investigations for eligibility for loans with the advice of the local banker and others and sets up the individual budget and plan for each family. In most of these cases, the trouble is not lack of income, alone, but lack of proper management of the farm and the home.

Personally, I like the Iowa plan by which the county medical society receives the money, pro-rates it to members and disciplines its own members.

As to Chiselling

The problem of chiselling, so-called, can best be handled so far as the doctors are concerned by their own medical societies. So far as the clients go, we have found that use of the service starts high. Apparently the people want to see if the service is really available as promised. In three months the calls are usually down to normal. In the case of real chisellers the superintendent makes a trip to see the client. It is ordinarily unnecessary for him to call twice.

We suggest that you formulate a plan, first, for the heavy load counties. If the plan works, expand it next year to other counties or change it as you see fit.

* * *

The whole matter was referred for action to the Committee on Low Income and Indigent Problems of which Dr. W. A. Coventry of Duluth is chairman.

Appropriation Endorsed

Dr. A. J. Chesley, secretary and executive officer of the State Department of Health, presented the budget of the Board for 1939, asked the special endorsement of the Council for $20,000 appropriation for purchase of pneumonia serum and also for a $12,000 appropriation for an industrial hygiene program, at the same Council meeting.

He explained that pneumonia serum is now supplied through a special appropriation from the Surgeon General of the United States Public Health Service and will not be available next year.

The Council endorsed the work of the Board in general and particularly its request for these appropriations.

MEDICAL YARDSTICK

There is only one basis for argument in any discussion of methods and payment for medical care. That is: will the resulting service to the patient be in line with the best standards of medical practice?

An excellent yardstick for good medical service has been provided by Mr. J. G. Crownhart, secretary of the Wisconsin State Medical Society, as a result of his own experience in medical organization work in Wisconsin and also of his recent careful survey of medical services in European countries. It is safe to say that any service which could be shown on the basis of experience—not of hopeful thinking—to measure up to this standard could be endorsed by the doctors. The yardstick follows:

Personalized Service

1. Responsibility for the service must be direct to the patient.

2. There must be a recognition of the fact that illness cannot be scheduled and that the physician must have time to do his work.

3. The needs of the individual sick man must govern the service.

4. Service to the patient must be a personalized service.

A fifth stipulation might be added to the effect that the physician must have ample opportunity and incentive for postgraduate study and research.

Obstacles

If it were possible for compulsory government medicine to measure up to this standard in fact, no conscientious physician could object to it. Experience in Europe, familiarity with bureaucracy in America have shown conclusively that systematized government medicine cannot possibly provide a service that measures up to the standard. Even if every government official connected with the service were invariably honest, conscientious and thoroughly qualified for his work, still there would be insuperable physical obstacles in the way that would prevent a personalized service in which the physician had sufficient time to do his work and in which the needs of the sick man alone governed the service.

Some other solution must be found for medical care in the United States.

PUBLIC HEALTH—Dr. Emerson

The following paragraphs from a recent address made in Michigan by Dr. Haven Emerson on "Public Health and Preventive Medicine" are highly pertinent to current discussions of medical care and its possible extensions. Their importance is emphasized by the fact that they come from a public health official and teacher rather than from a typical representative of the private practitioner of medicine.

Says Dr. Emerson:

> Health is much more than the freedom or recovery from disease. It is a way of life, a balance, a compromise, sometimes worth sacrificing other desires or ambitions to achieve, and the most precious possession a person may lose or feel compelled to give up in exchange for other ambitions. Health is a quality of man the individual, not of that amorphous, helpless, blundering social entity, the Public.
>
> There are but six functions which modern civil government has found appropriate and necessary for a department of health. Whatever nation, state, city or rural area has created a department of health to be devoted to the application of the science of preventive medicine for social ends, it has found that vital statistics, communicable disease control, the hygiene of maternity, infancy and childhood, laboratory service, sanitation, and health education include all essential public health services. These are all auxiliary or supplementary activities, the benefit of which comes to the client or patient of the private practitioner.
>
> Each of these funtions of a public health department is necessary to make more effective, not to supplant, the work of the family physician.
>
> For the hygiene of maternity, infancy and the child, if we had a consistently educated community of families, there would be no need for concern of the health officer with such matters.
>
> Certainly no public officer, elected or appointed, can be presumed to have such interest or responsibility for the health of the expectant mother as she herself and her husband should have, and should know enough to ask for from their physician.
>
> It ought to be as much taken for granted to call upon a physician to learn how to keep a baby or its mother well as to ask him to the home to diagnose a fever or set a broken bone.
>
> The health officer of a community is its hired teacher, obliged to advertise to the public the benefits to be expected from using the local practitioner as an expert in normal childhood, as well as calling on him for medicines or operations.
>
> It ought to be the medical practitioners, familiar as they are with the needs for health teaching and service among their patients, who should formulate the substance and sequence of the public educational program, and press upon the health officer to do more and better teaching, and teaching that will bring about personal health of multitudes.—*Journal of the Michigan State Medical Society.*

SAFETY CONFERENCE—DULUTH

Once each year for fifteen years the St. Louis County Medical Society has taken charge of one of the five annual Industrial Conferences staged annually by the Duluth Chamber of Commerce.

Representatives from ninety-seven different industries and business firms attend this conference and the program on industrial medicine arranged by the physicians is a high point in the year's safety program.

Medical head-liner this year was Dr. George Earl, president of the Minnesota State Medical Association, who talked to an audience of 1,000 industrial workers and safety leaders at the Hotel Duluth on the subject "Social Medicine."

> "Dismiss from your minds" Dr. Earl told them, "the idea that the doctors have any prejudice against the state caring for those who cannot care for themselves.
>
> "There is now socialized medicine, if you wish to call it that, to the extent that more hospital beds in the state are maintained by government than are maintained by private sources *but the movement to socialized medical care for all does not spring from democratic sources.* Often it is associated with totalitarian government philosophies as a part of their program to extend administrative power."

CAN A DREAM BECOME A REALITY?

(Monthly Editorial Prepared by the Medical Advisory Committee)

Several years ago three members of our Association sat in a room and pondered their obligations toward the new baby that they had taken upon themselves to nurture and rear, little knowing the immense task, the wellnigh insurmountable difficulties that were before them, but with the hope that as time passed their duties would be made clear to them. These duties have now become a pleasure and a happiness because the dream of yesterday has become a reality of today.

Your Medical Advisory Committee, as the New Year dawns, finds itself working whole heartedly with the insurance companies that protect and indemnify our members. It has an excellent working arrangement with a Committee of the Minnesota State Bar Association. The membership is coming more and more to value the worth of a closeknit, working agreement with each other.

Malpractice litigation is becoming less and less. Biased, unscrupulous, professional testifiers are being eliminated from the picture in lawsuits and a whole-hearted attitude is being assumed by one member toward another in the courts.

A recent experience in Court shows the truth of the statement above. Picture a medical witness testifying before four of his colleagues in a suit involving the work of a member of his profession. In calm, quiet tones the questions are put before him by the defendant's and plaintiff's lawyers. No bickering, but a plain statement of true facts is elicited from the answers given. The jury did get the proper impressions from such testimony and the dignity of the two professions, law and medicine, was upheld before both Court and Jury. Truthful testimony injures no doctor. It is the sly insinuations by the lawyer and half-truths told by the witness doctor that spoil the best reputations.

The dreamed of ideal is becoming in truth a reality. B.J.B.

SECOND CONGRESS

Among several programs of unusual interest to be staged in connection with the 86th Annual Meeting of the Minnesota State Medical Association at the Minneapolis Auditorium May 31, June 1 and 2, is the second Congress of Allied Professions.

With an extended national health program about to be introduced into Congress, with new plans for medical practice in the air, with physicians under fire from many quarters, this second Congress assumes a great importance in the history of Minnesota's progress in medicine and public health.

The program for the Congress will include an outline of the attitude and plans of the Administration in Washington, also of the current program in Minnesota and practical possibilities for its extension. There will be a discussion likewise of various aspects of sickness insurance, both voluntary and compulsory. Speakers are being chosen very carefully to present different points of view and the program will consume an entire day of program time during which there will be no scientific sessions beyond the regularly scheduled exhibits and demonstrations.

The interest of physicians in public health education will be graphically demonstrated in a public health exposition which will occupy the ground floor of the Auditorium and which will be open to the public during the entire three days of the meeting. Every phase of health protection and disease prevention with which the average person should be acquainted will be demonstrated in this exposition. Appropriate committees of the state association will be responsible for the material shown. They will have the enthusiastic coöperation of all official and voluntary agencies interested in special phases of public health work.

MINNESOTA STATE BOARD OF MEDICAL EXAMINERS

License of Two Hallock Physicians Suspended for Eighteen Months

In the Matter of the Revocation of the License of Kenneth Vincent Overend, M.D.

In the Matter of the Revocation of the License of Fred Earl Myers, M.D.

The Minnesota State Board of Medical Examiners at a meeting held on December 16, 1938, suspended for eighteen months, the license to practice medicine and surgery held by Kenneth Vincent Overend, M.D., and Fred Earl Myers, M.D., of Hallock, Minnesota.

Drs. Overend and Myers practiced together at Hallock and following an extended investigation by the Medical Board they were cited to show cause why their licenses as physicians should not be revoked for conduct unbecoming a person licensed to practice medicine and detrimental to the best interests of the public. Both of them entered pleas of guilty before the Board. The evidence disclosed numerous cases of bilateral salpingectomies and other surgical procedures, some of which resulted in the miscarriage of the patient.

Mankato Physician's License Revoked

In the Matter of the Revocation of the License of Arthur W. Eckstein, M.D.

The license to practice medicine and surgery held by Arthur W. Eckstein, M.D., Mankato, Minnesota, was revoked by the Minnesota State Board of Medical Examiners on December 16, 1938. Dr. Eckstein was found guilty by the Medical Board of "immoral, dishonorable and unprofessional conduct," and, specifically with procuring, aiding and abetting a criminal abortion.

In 1932 Dr. Eckstein was before the Board on a similar charge and was reprimanded and placed on probation. In 1934 Dr. Eckstein pleaded guilty in the District Court at Mankato to the crime of abortion and was sentenced to two years at hard labor in prison. Upon his release he pleaded with the Medical Board for a chance to take the examination for a new license. Numerous physicians in Mankato endorsed him and a license was finally issued. Dr. Eckstein's first license was revoked in May, 1934.

In the present case Dr. Eckstein was seen on October 17, 1938, in the act of throwing a package over the Minnesota River bridge at Mankato. Subsequent investigation disclosed the contents as a fœtus, with the head severed from the body. He was arrested on the next day charged with abortion. Eight witnesses testified before the Medical Board. The criminal case at Mankato has not been disposed of.

License of Lake City Physician Suspended for Five Years

In the Matter of the Revocation of the License of Gottfried Schmidt, M.D.

The Minnesota State Board of Medical Examiners, on December 16, 1938, suspended for five years the license to practice medicine and surgery held by Gottfried Schmidt, M.D., Lake City, Minnesota. Dr. Schmidt was found guilty by the Medical Board of advertising "professional superiority to, and greater skill than, that possessed by fellow physicians and surgeons" and of "conduct unbecoming a person licensed to practice medicine and detrimental to the best interests of the public."

Numerous complaints had been received by the Medical Board as to the methods used by Dr. Schmidt in making a diagnosis and also in his manner of treating ailments. Letters also had been referred to the Board that were written and mailed by Dr. Schmidt, in his practice, to patients and others. These letters in the opinion of the Board are highly improper. Dr. Schmidt attempted to diagnose diseases by having the patient place some saliva on a piece of paper. Out of town patients mailed this paper to Dr. Schmidt at Lake City. He then proceeded to treat the patient by medicine sent through the mail. He also stated that he had a machine with which he could broadcast treatments.

Dr. Schmidt was admonished by the Board in 1936 to refrain from these practices. However, he persisted and the citation resulted. Dr. Schmidt was born in Minnesota in 1871 and graduated in medicine from the University of Minnesota in 1903.

Medical Board Orders the Kru Gon Company to Cease Operations in Minnesota

Following an investigation, conducted by the Minnesota State Board of Medical Examiners, The Kru Gon Company of Muncie, Indiana, was ordered to cease operations in the State of Minnesota on December 6, 1938. The investigation discloses that this company had a representative, one Edward L. Pepper, seventy-two years of age, who holds no license to practice any form of healing in the State of Minnesota, operating in the Rask Drug Store at Willmar, Minnesota. When an agent of the Medical Board asked Mr. Pepper what conditions Kru Gon Capsules were recommended for, he replied: "Stomach, liver and kidneys." When he was asked if they were of any value in the treatment of a gall bladder condition, he replied, "Absolutely." When he was asked what effect they would have upon gall stones, he replied that Kru Gon capsules would "dissolve" them. The drug store received 20 per cent commission on the amount taken in by the Kru Gon man, with the company paying the agent a salary. Mr. Pepper admitted that he knew nothing about the ingredients of the capsules and that while he had been with the company for 10 years, he had never been to the home office at Muncie, Indiana, nor did he know anything about the company. Advertising material was published in the local newspaper to stimulate business and contains many statements of a very questionable nature. When Mr. Pepper was advised that a complaint would be filed charging him with a violation of the Medical Act, and that this method of doing business would not be tolerated in the State of Minnesota, the company advised that they were ceasing operations at once.

The State Board of Medical Examiners is of the opinion that the acts in this case constitute a violation of the Minnesota law against fraudulent, misleading and deceptive advertising, as well as a violation of the Medical Act and the Basic Science Law. The Board respectfully requests that it be immediately notified if this company, or any representative of it, operates at any place in the State of Minnesota. To the Board's knowledge this company has operated in Winona, Duluth, Hibbing, Faribault and Mankato, in addition to Willmar.

Chiropractor Re-sentenced to a Term of Not to Exceed Eight Years in Prison

State of Minnesota vs. Herman V. Feenstra

On November 21, 1938, at Glencoe, Minnesota, Judge Joseph Moriarty sentenced Herman V. Feenstra, sixty-five years of age, to a term of not to exceed eight years in a Minnesota penal institution. Feenstra, an itinerant, unlicensed chiropractor, had been sentenced, on August 10, 1938, to a term of not to exceed four years in prison, following his plea of guilty to an information charging him with the crime of abortion. The investigation disclosed that Feenstra had a prior conviction in the Circuit Court at Brookings, South Dakota, for a similar crime, and under the Minnesota law, his sentence was doubled. Feenstra was first arrested in Minnesota, on August 8, 1938, by the late Sheriff Beihoffer of Glencoe.

At the time of his arrest, Feenstra stated that he graduated from the Davenport School of Chiropractic in 1922. He stated that he practiced chiropractic, for a time, at Elkton, South Dakota, but lost his license because of performing abortions. The records of the Circuit Court of Brookings, South Dakota, show that Feenstra forfeited a $2,500.00 cash bond on January 19, 1938, at which time he was under arrest on a charge of rape. Feenstra never held any license to practice any form of healing in the State of Minnesota.

UNIVERSITY OF MARYLAND
LIBRARY
Founded 1813
SCHOOL OF MEDICINE

Dr. Frederick P. Arny of Preston, has been appointed coroner of Fillmore County.

* * *

The engagement has been announced of Miss Lucille Quinn, of Minneapolis, and Dr. John R. Meade of Saint Paul.

* * *

Dr. A. L. Abraham of Duluth, was the principal speaker at a meeting of the Arrowhead X-Ray Technicians Society held early in December. He spoke on "Some Technical Problems."

* * *

Dr. J. D. Camp of Rochester, was the toastmaster at the banquet of the Twin Cities Society of X-Ray Technicians held December 10 at the Curtis Hotel in Minneapolis.

* * *

Dr. L. M. Randall and Dr. W. B. Hunt of Rochester, were in charge of the program for the Travel Club, composed of midwest obstetricians and gynecologists, which met in Rochester on December 3.

* * *

Dr. Theodore W. Stransky, formerly located at Mandan, North Dakota, has returned to his native city, Owatonna, where he has opened offices for the practice of medicine.

* * *

Dr. Leslie G. Seebach of Red Wing, who has been an interne at Ancker Hospital, has qualified for appointment to the grade of assistant surgeon in the United States Naval Medical Corps, with the rank of lieutenant.

* * *

Dr. Charles F. Code, recent recipient of the Theobald Smith Award, has been appointed instructor in physiology at the University of Minnesota for the current year. Dr. Code has worked the past three years at University College, London, and at the Mayo Foundation.

* * *

The engagement is announced of Miss Helen Butler, daughter of Mrs. R. N. Goldthwaite of Fort Sill, Oklahoma, and the late Colonel Clifton M. Butler, to Dr. Carl N. Giere, son of Dr. E. O. Giere, Saint Paul. Dr. Carl Giere is a University of Minnesota Medical School graduate.

* * *

Correction: In the General Interest section of the December number Dr. Walter H. Judd, medical missionary, was erroneously stated to be the son of the late Dr. E. Starr Judd. Dr. Walter Judd is not related to the late Dr. Judd, although the family name is the same.

Dr. Milo M. Loucks, formerly of Flandreau, South Dakota, has located in Rushmore for the practice of medicine. He was Assistant Surgeon General of the South Dakota area of the United States Army for six years, and previous to that was an instructor at the University of Minnesota.

* * *

The docks and elevators Section of the Duluth Chamber of Commerce Industrial Safety Conference which met on December 7, at the Hotel Duluth, was addressed by Dr. G. A. Hedberg of Nopeming, on the subject of "Dust and Lungs." Other physicians appearing on the program, which was arranged by the St. Louis County Medical Society, were Dr. A. G. Athens, Dr. M. H. Tibbetts, Dr. F. T. Elias and Dr. Gordon MacRae. Dr. G. A. Earl of Saint Paul spoke on "Social Medicine."

* * *

Dr. Charles F. McComb, Duluth, eight times elected coroner of St. Louis County, retired the first of the year at the age of eighty-one. He will be succeeded by Dr. John W. Ekblad, who was elected to the office last November.

Dr. McComb was president of the Minnesota State Medical Association in 1888, was the first president of the Interurban Academy of Medicine and was twice president of the St. Louis County Medical Society since beginning practice in Duluth in 1883.

* * *

Medal Presented to Dr. Meyerding

Formal public presentation of the medal and scroll for distinguished service to the Minnesota State Medical Association was made to Dr. E. A. Meyerding at the state association banquet in connection with the 85th Annual Meeting in Duluth, June 30.

The presentation took place immediately after the Council action instituting the honor and before the committee appointed had selected the emblem.

A hand illuminated parchment and a gold medal bearing the seal of the association were later completed and inscribed in accordance with orders of the committee and actual presentation took place December 15 at a luncheon meeting of the Council at the St. Paul Hotel.

Dr. A. W. Adson, Rochester, chairman of the special committee, made the presentation. Dr. C. A. Stewart, Minneapolis, and Mr. W. W. Will, Bertha, the other committee members, also President J. M. Hayes of Minneapolis, Dr. George Earl, St. Paul, and Dr. W. F. Braasch, Rochester, recalled Dr. Meyerding's important contributions to medical organization in Minnesota and joined in praising the decision to award to him the first honor of this kind ever bestowed in Minnesota.

A similar medal and scroll will be awarded to other leaders who may from time to time merit the honor.

REPORTS and ANNOUNCEMENTS

MEDICAL BROADCAST FOR JANUARY

The Minnesota State Medical Association Morning Health Service.

The Minnesota State Medical Association broadcasts weekly at 11:00 o'clock every Saturday morning over Station WCCO, Minneapolis (810 kilocycles or 370.2 meters), and Station WLB, University of Minnesota (760 kilocycles or 395 meters).

Speaker: William A. O'Brien, M.D., Associate Professor of Pathology and Preventive Medicine, Medical School, University of Minnesota.

The program for the month will be as follows:

January 7—Pneumonia.
January 14—Sciatica.
January 21—Anorexia Nervosa.
January 28—Heredity and Dental Caries.

MISSISSIPPI VALLEY MEDICAL SOCIETY 1939 ESSAY AWARD

The Mississippi Valley Medical Society offers a cash prize of $100.00, a gold medal and a certificate of award for the best unpublished essay on a subject of interest and practical value to the general practitioner of medicine. Entrants must be members of the American Medical Association. The winner will be invited to present his contribution before the next annual meeting of the Mississippi Valley Medical Society at Burlington, Iowa, September 27, 28, 29, 1939. All contributions MUST NOT exceed 5,000 words, be typewritten in English in manuscript form, submitted in five copies, and must be received NOT later than May 1, 1939. Further details may be secured from Harold Swanberg, M.D. Secretary, Mississippi Valley Medical Society, 209-224 W. C. U. Building, Quincy, Ill.

POSTGRADUATE INSTITUTE OF THE PHILADELPHIA COUNTY MEDICAL SOCIETY

The fourth annual Postgraduate Institute of the Philadelphia County Medical Society will be held in the Bellevue-Stratford Hotel, Philadelphia, during the week beginning March 13, 1939. The program will consist of some eighty-six clinical lectures on the general subjects of blood dyscrasias and metabolic disorders.

Philadelphia has always been in the van of medical progress and the yearly institute, at which last year there was a registration of 1,787, affords an opportunity for the several medical schools located in the city to present the results of their investigative labors.

The Philadelphia County Medical Society, Twenty-first and Spruce Street, Philadelphia, may be addressed for particulars.

EAST CENTRAL MINNESOTA

The East Central Minnesota Medical Society held its annual meeting on Monday, December 12, 1938, in Cambridge, Minnesota. Dr. Arthur Neumeier and Dr. Abraham Gunz of Lindstrom and Dr. Gladys Trommold of Anoka were elected to membership in the Society. Dr. Raymond Gully, formerly associated with the Nicollet-Le Sueur Medical Society was accepted as a transfer. The Society elected to honorary membership Dr. Thomas Zeien of North Branch.

The following officers were elected for the coming year: Dr. A. L. Arends, Sandstone, president; Dr. Walter P. Gardner, Anoka, vice president; Dr. Claire M. Ness, Cambridge, secretary-treasurer; Dr. H. C. Cooney, Princeton, delegate; and Dr. George Schlesselman, Anoka, alternate delegate.

Dinner was served and a scientific program was presented by guest speakers. Dr. Erling Platou of Minneapolis spoke on "Convalescent Sera as Therapeutic Agents," demonstrating with movies the technic of preparing the sera. Dr. Gordon Kammann of Saint Paul talked on "Neurosis."

MINNESOTA SOCIETY OF INTERNAL MEDICINE

Dr. Moses Barron of Minneapolis was elected president of the Minnesota Society of Internal Medicine at a meeting held in Rochester on December 3. Dr. R. M. Wilder of Rochester was elected vice president and Dr. Max H. Hoffman of Saint Paul was reelected secretary-treasurer. D. G. B. Eusterman of Rochester is chairman of the Executive Committee; Dr. E. L. Tuohy, Chairman of the Education Committee. Minneapolis was selected as the place for the spring meeting.

NICOLLET-LE SUEUR COUNTY SOCIETY

At the annual meeting of the Nicollet-Le Sueur County Medical Society, held in Le Sueur on December 13, Dr. Nels Sonneyson of Le Sueur was elected president and Dr. P. J. Hiniker of Le Sueur, secretary. Dr. Burton Grimes of St. Peter was elected vice president.

Dr. Hobart Johnson, who has been a medical missionary for several years, gave a talk on "Practice of Medicine in Africa."

RAMSEY COUNTY SOCIETY

The following officers were elected at the meeting of the Ramsey County Medical Society, held Monday night, November 28, in the Lowry Medical Arts Building, Saint Paul: Dr. George N. Ruhberg, president-elect for 1940; Dr. R. B. J. Schoch, president; Dr. Arnold P. Gruenhagen, vice president; Dr. J. Allen Wilson, secretary-treasurer.

ST. LOUIS COUNTY SOCIETY

The annual meeting of the St. Louis County Medical Society was held on December 8 in Duluth. Dr. T. L. Chapman of Duluth, was elected president-elect; Dr. Gage Clement, Duluth, president; Dr. Andrew Sinamark, Hibbing, vice president, and Dr. Gordon MacRae, Duluth, secretary-treasurer.

Mr. J. G. Crownhart, executive secretary of the Wisconsin Medical Association, who was the principal speaker at the dinner, discussed the subject, "Socialized Medicine."

STEARNS-BENTON COUNTY SOCIETY

The Stearns-Benton Medical Society held its annual dinner at the Breen Hotel in St. Cloud on December 15. The following officers were elected: Dr. C. S. Donaldson, Foley, president-elect; Dr. W. T. Wenner, St. Cloud, president; Dr. E. M. Kingsbury, Clearwater, vice president; Dr. J. N. Libert, St. Cloud, secretary-treasurer.

UPPER MISSISSIPPI SOCIETY

The next meeting of the Upper Mississippi Medical Society will be held at the Ransford Hotel, Brainerd, Saturday, January 28, 1939. The following program will be given beginning at 3:30 p. m.:

Dr. Gordon Kamman, Saint Paul
"Vitamins and Encephalitis"

Dr. Viktor O. Wilson, Minneapolis
"The Basis for a Maternal and Child Health Program"

Dr. Chester A. Stewart, Minneapolis
"Nutritional Problems in Infancy"

Dr. O. J. Campbell, Minneapolis
"Some Observations on the Care of Fractures"

Dr. H. E. Michelson, Minneapolis
"Dermatology"

IMMUNE GLOBULIN (Human)

A preparation of globulins made from human placental blood and containing immune factor or factors against measles. The immunizing potency of the product is determined on the basis of the diphtheria antitoxin titer of the placental blood. Immune globulin (human) is useful in the prevention and modification of measles. It is equivalent in usefulness to convalescent serum but has the advantage of universal availability. It has the disadvantage of producing reactions not always mild. Most reactions, however, can be avoided by administration of the proper dosage. It is useful in the prevention of measles in institutional cases in larger doses than those given for modification. Protection should not be attempted until definite exposure has taken place. Immune globulin (human) has also been used (with caution) in the treatment of measles.

WOMAN'S AUXILIARY

Mrs. J. F. Norman, Crookston, *President*
Mrs. A. A. Passer, Olivia, *Editor*

GREETING FROM THE STATE PRESIDENT

'Tis said, "It is never too late for a good wish." So, with the Christmas holidays disappearing only just around the corner, I welcome an opportunity to express again my sincere wish for a happy, and a prosperous New Year to every individual member of the Women's Auxiliary.

May the coming year bring to each one of us, strength and courage to face our own responsibilities without faltering.

Let us encourage the medical profession—our husbands—in the face of a trying situation to keep their ideals untarnished, to preserve the tolerance, and sympathetic understanding, the dignity and courtesy that has always made them a distinguished group among all men.

May we have renewed faith in ourselves, and in each other.

Elizabeth B. Roberts,
State President

REPORT OF THE PRESS AND PUBLICITY CHAIRMAN

On November 8, members of the Washington County Medical Auxiliary met with their president, Mrs. J. W. Stuhr, presiding. This was their first meeting of the season. Five dollars was donated to the Scout Fund and five dollars to the High School "Radio Educational Project." A committee was appointed to outline the plans for the work of the year.

* * *

At the November meeting of the Women's Auxiliary to the St. Louis County Medical Society, a turkey luncheon was served at one o'clock at the home of Mrs. D. C. Rood. Mrs. M. G. Gillespie, the president, presided. The meeting was followed by a musical program given by Mrs. Anderson Hilding, violinist, and Mrs. Donald MacGregor, pianist. A rummage sale was held in November under the supervision of Mrs. P. S. Rudie, Mrs. M. G. Gillespie, Mrs. C. M. Smith, and Mrs. Harry Klein. The proceeds from this sale are used for the philanthropic activities, which includes the distribution of Christmas baskets.

* * *

The Hennepin County Auxiliary has had a most active season so far this year. On Wednesday, December 14, Mrs. F. A. Erb was hostess to the Hennepin County Auxiliary at Sarahurst, convalescent home for patients discharged from the Glen Lake Sanatorium, which is maintained by the Hennepin County Tuberculosis Association. The hours were from 2 to 4. Friday, December 2, the Hennepin County Auxiliary had its annual Christmas party in the lounge of the Medical Arts Building. A silver offering went for the rehabilitation home, Sarahurst. Mrs. A. E. Benjamin, Mrs. E. S. Strout, Mrs. J. M. Hall and Mrs. R. R. Noice comprised the hospitality committee. Christmas carols and Christmas legends were heard. New members of the Hennepin County Auxiliary were honored at a tea which was given in October at the home of Mrs. H. M. Lee, 4848 Russell Avenue South. The new members and officers were the guests of honor. Hennepin County officers for the year are: Mrs. R. R. Crammer, president; Mrs. E. S. Mariette, president-elect; Mrs. C. E. Willcutt and Mrs. J. S. Reynolds, vice presidents; Mrs. Harold G. Benjamin, recording secretary; Mrs. C. W. Laymon, corresponding secretary; Mrs. J. P. Hiebert, treasurer; Mrs. R. R. Noice, auditor, and Mrs. H. B. Hannah, custodian. Mrs. W. J. Byrnes is president emeritus and also serves as parliamentarian; Mrs. J. D. Lyon is historian and Mrs. J. S. Milton, editor.

Committee chairmen include Mmes. L. R. Boies, J. M. Neal, C. D. Creevy, J. M. Hayes, A. H. McFarland, P. J. Schultz, W. G. Beckman, F. A. Erb, J. C. Davis, Leo W. Fink, J. A. Watson, Hugh Tunstead, J. M. Hall, G. T. Nordin, W. W. Moir, Martin Nordland and J. A. Polzak.

At the October meeting the members heard a talk on current books given by Mr. J. H. Kittleson. On November 18 and 19 the auxiliary sponsored their annual sale of articles made by patients at Glen Lake Sanatorium, proceeds going to the makers of the articles. The Philanthropic Committee includes Mrs. J. C. Davis, chairman, assisted by Mrs. N. H. Lufkin, L. F. Richdorf, J. C. Miller, L. M. Larson, F. L. Jennings and Donald McCarthy.

* * *

Nearly 10,000 talks were written by high school students throughout the state on the subject, "Tracking Down the Foe of Youth" in a contest conducted by the Minnesota Public Health Association in coöperation with the Women's Auxiliary of the Minnesota Medical Association. This was the eighth annual contest in which the Auxiliary participated. Mrs. Martin Nordland, Minneapolis, former state president, represented the Auxiliary on the committee of judges.

The best talk from each high school, selected by a preliminary public speaking contest, was entered in the state contest. From the manuscripts submitted, the judges selected the six talks they considered best, which were presented by their authors in a series of special broadcasts over WCCO during the week of December 12. Competing in the broadcasts for the radio plaque and silver cup awarded by the Auxiliary, were John Christianson, Moorhead; Robert Schwartau, Goodhue; Helen Kessler, St. Joseph's Academy, Saint Paul; Rosemary Perkins, Technical High School, St. Cloud; Jean Esala, Aurora; Betty Wallin, Red Lake.

Winners in the finals were John Christianson, Junior High, Moorhead; and Betty Wallin of the Red Lake Senior High School, located on the Indian reservation.

The following article is from the newsletter of the Woman's Auxiliary of the American Medical Association in which Mrs. Charles C. Tomlinson, the national president, tells of her visit to Minnesota the latter part of September:

"On Sunday, September 26, I left for Minneapolis to attend the Minneapolis Executive Board meeting—a very splendid meeting presided over by Mrs. W. B. Roberts, whose leadership assures a most successful year for Minnesota. Minnesota reports a steady increase of activity and membership, with twenty-five active units and over 1100 members. It was my privilege to share honors with Dr. Hayes, president of the Minnesota State Medical Society, in addressing the meeting. The interest and coöperation of this group was well attested by the attendance. When I entered the well-filled dining room of the Country Club, I wondered if I had misunderstood the invitation and was finding myself at a state convention. Again I saw many familiar national Auxiliary figures—Mrs. Martin Nordand, Mrs. S. S. Hesselgrave, Mrs. John Catlin, Mrs. Wm. Byrns, and our own past national president and present finance chairman, Mrs. James Blake. Through the courtesy of Dr. W. B. Roberts it was my pleasure to see the beautiful city of Minneapolis at its best. The restful lakes, beautiful homes, shrubbery and trees, already tinted to indescribable hues by the frost of Indian Summer. Tuesday morning, September 27, at the invitation of Dr. E. A. Meyerding, secretary of the Minnesota Public Health Association, I attended a breakfast given in Saint Paul, at the Hotel Lowry, honoring Mrs. Saidie Orr Dunbar, president of the General Federation of Women's Clubs. In the afternoon I was honor guest at a beautiful tea given by the Ramsey County Auxiliary at the home of Mrs. Edward Schons. It was a real joy to meet and know Mrs. A. E. Nichols, president of the Ramsey County Auxiliary, and the other members of this progressive group. A most enjoyable visit at Hopkins, in the home of Mrs. James Blake, completed my sojourn to Minnesota."

* * *

On December 18 and 19 the members of the Women's Auxiliary of the Ramsey County Medical Society sponsored the play, "The Dream of a Clown," which was given at the Saint Paul Auditorium. The proceeds from this play will be used for various philanthropic purposes which will be announced in the next issue.

The Auxiliary received a nice response from members of the Ramsey County Medical Society and cooperation on the part of many prominent citizens and Saint Paul officials in this rather unusual performance. All parts were taken by members of the male sex and no little unexpected talent was displayed. The audience was kept in a constant state of laughter at the appearance and behavior of the actors.

MINNEAPOLIS SURGICAL SOCIETY

Stated Meeting, Thursday, November 3, 1938

RECENT ADVANCES IN THE SURGERY OF THE NECK

Martin Nordland, M.D.
Minneapolis

In the discussion of recent advances in the surgery of any region it is customary to review the history of the subject. Outside of the story of goiter, the history of the treatment of the various disorders about the neck resolves itself into the recording of occasional developments of certain new procedures. The treatment of the thyroglossal duct cyst by Sistrunk and the accidental development of the operation of tenotomy for the relief of symptoms from cervical rib by Adson are conspicuous examples. Patients with these disorders or pulsion diverticuli of the pharynx are encountered so seldom by the surgeon of average experience that mistakes in diagnosis are common and surgical mismanagement is frequent. This discussion will be limited to a brief review of the treatment of these conditions and to some of the newer developments in the management of goiter.

The surgeon has some important responsibilities beyond the immediate mortality which are peculiar to the treatment of the disorders of the neck and which are not common to the surgery of other regions. In the block dissection of the glands of the neck, because of the motor paralysis, he must protect and avoid the descending hypoglossus nerve; in the treatment of branchiogenetic and thyroglossal duct cysts he must consider and be responsible for recurrences. In the surgery of the thyroid he must be concerned not only with the mechanical complications such as injury to the parathyroid bodies and laryngeal nerves, but also he must be mindful of a good functional result. To deal with these responsibilities, he must be thoroughly familiar with the anatomy of the neck and be informed concerning the problems of hypo- and hyperthyroidism. The appearance of the scar is not the least of the surgeon's responsibilities in the surgery of this region. Patients are exacting. They demand an invisible scar corresponding to the natural folds of the neck, and justly so.

Thyroglossal Duct Cysts and Fistulæ

How rarely the patients with thyroglossal duct cysts are encountered by the surgeon of average experience is emphasized in a review of the technic of the treatment of this condition which was published by Sistrunk in 1928. He stated in his report that in 86,000 consecutive patients examined in the Mayo Clinic, only thirty-one thyroglossal duct cysts were found. Lack of thorough understanding of the mode of development of such cysts and of the anatomy of the base of the tongue and surrounding structures has frequently led to a wrong diagnosis and improper surgical management. It should not be difficult to make a diagnosis of such cysts with this knowledge of their congenital origin. The tumor is usually a firm cystic mass in the midline of the neck near the hyoid bone or the thyroid cartilage. The duct which runs from the cyst to the hyoid bone is usually felt. Sistrunk pointed out that operation for the cure of thyroglossal duct cysts and fistulæ are unsuccessful unless the epithelium-lined tract running from the cyst to the foramen cecum of the tongue is completely removed. He further pointed out that it is better not to attempt to isolate the duct above the hyoid bone because it is so small and friable. He suggested it was better to include some of the tissue on all sides around the duct from the hyoid bone to the foramen cecum. It is a harmless operation and, properly performed, prevents recurrences and results in 100 per cent of cures.

Pharyngeal Pulsion Diverticuli

The treatment of pulsion diverticuli of the pharynx recently developed by Chevalier Jackson is worthy of brief consideration. The technic he has recommended makes it possible for the surgeon of average experience to deal with this condition with good results. He has suggested the use of the esophagoscope in the dissection of the sac. With this aid the pouch is found more quickly and the contaminating contents can easily be removed before the sac is excised. This makes a cleaner operation. Jackson has found that an accurate dissection and excision of the cleaned sac and a closure with the finesse of arterial suture results in a safe one-stage operation. He further recommends a transverse incision in the natural fold of the neck. This, he contends, makes for better support and for inconspicuous healing.

Cervical Rib

The first important paper on the treatment of cervical rib was written in 1740 by Hunauld. More than 100 years later Gruber presented the second important contribution on this subject. These, and all subsequent articles, up to the time of the work of Adson and Coffey in 1927, recommended the complete or partial removal of the rib or section and removal of the prolongation for surgical relief. While operating upon a patient, they were compelled to discontinue after they had proceeded as far as section of the insertion of the scalenus anticus muscle, intending to complete the procedure in a second stage. To their surprise, the patient was completely relieved of symptoms by simple tenotomy and since then they have practiced this as the operation of choice with much success. When possible, this procedure is better than removal of the cervical rib, in that it is simpler and avoids traction upon the brachial plexus. Simple tenotomy obviates the temporary palsy of the brachial plexus which often happens in the removal of the cervical rib and complete relief of the symptoms is obtained. The procedure is a most notable contribution to the operative relief of cervical rib pressure.

Thyroid Disease

Goiter has been a familiar malady for thousands of years. Through the work of Bilroth, Kocher, Halstead, Mayo and deQuervain, it is now more than fifty years since operations on goiter have acquired a position among the accepted procedures of surgery. The mortality rate at the present time is less than 1 per cent. A student of the history of this subject will find that some surgeons in the last century achieved almost as much in the surgical management of goiter as is being accomplished today. Much of the recent study of thyroid disease has been concerned with endocrine interrelationships, iodine in its relation to the diagnosis, prophylaxis and treatment of goiter, blood iodine and the evaluation of the basal metabolic rate. The value of polar ligation in the two-stage operation for hyperthyroidism has been recently re-established by Lahey. He has also made a valuable recent contribution in his introduction of the intratracheal catheter for anesthesia in the management of intrathoracic goiter. Total ablation of the thyroid in the treatment of heart disease has been developed since 1932. During the past five years there has been continually a repetition of attempts to cure goiter by other means than surgery. Most conspicuous of these is the application of roentgenotherapy. So far, it has not made a significant impression.

Iodine, Prophylaxis and Treatment

Although the clinical use of iodine is probably a medical problem, the surgeon who is handling patients with thyroid disease is repeatedly called on to state whether or not iodine should be used in a given case. According to Dinsmore the clear-cut indications for the use of iodine are:

1. Small doses during pregnancy, especially to women who have enlargement of the thyroid.
2. As a prophylactic measure in doses of 10 mgm. a week to school children.
3. For the adolescent boys and girls who have simple goiters.
4. As a pre-operative medication in all patients with hyperthyroidism regardless of the type of the gland.
5. In cases of residual or recurrent hyperthyroidism.
6. As a therapeutic test in borderline cases.

Blood Iodine

Many studies have recently been made relative to the value of blood iodine. Although the procedure may have distinct diagnostic value, its application is limited. Certainly there is no indication for its use in the presence of frank hyperthyroidism. It may, however, be of some value in making a differential diagnosis when it is difficult to determine the basal metabolic rate, such as in hypertension, in young children, and in encephalitis. In spite of the simplification of the technic, it is still a rather difficult laboratory procedure. In many of the borderline cases, it has been pointed out that the chief value comes in finding a normal blood iodine. Also, there are patients who have clear-cut hyperthyroidism with normal blood iodine.

Multiple Stage Operations

Lahey has re-established the importance of polar ligation and has emphasized its value. Mortality in the surgery of hyperthyroidism is due either to some lesion of the heart or kidneys or occasionally to some lung complication. A few of these patients die from postoperative crisis. It is in this last group that the two-stage operation should be employed. The use of Lugol's solution, introduced by Plummer in 1923, was a great advance in the management of hyperthyroidism. In spite of its employment in the preoperative preparation of this group of patients, there is still a group of about 5 per cent of patients with hyperthyroidism who cannot be made satisfactory surgical risks by the prolonged medical treatment. Polar ligation or a two-staged operation is imperative under such circumstances. The decision to perform a multiple stage procedure may be made preoperatively or after the operation has begun. A patient with marked hyperthyroidism whose pulse rate cannot be reduced by the administration of iodine and rest should have a two-stage operation. No patient should be operated upon for goiter in a one-stage operation who is losing weight. Patients with recent vomiting and diarrhea associated with an elevated basal metabolic rate usually need a two-stage operation. During the operation the patient with a progressively rising pulse and an increasing pulse pressure should have a two-stage operation. If, during the operation, technical difficulties are encountered, such as excessive bleeding, consuming much time, a two-stage operation should be contemplated. Lahey asserts that 22 per cent of the patients in his clinic are subjected to the preliminary polar ligation. He reasons that a patient with hyperthyroidism dying following a one-stage operation, might have lived with a two-stage resection; and, further, that a patient dying after a two-stage resection might have lived with a preliminary ligation of one or both of the superior poles.

Intrathoracic Goiter

In the surgical management of the intrathoracic goiter, Lahey has recently advocated intratracheal anesthesia. Whether one employs ether, nitrous oxide gas, ethylene, or cyclopropane, the most recent anesthesia which is now being used, it then becomes purely a matter of the anesthetist's choice so long as an intratracheal catheter has been introduced.

In all intrathoracic goiters in which there is any considerable narrowing of the trachea and in which the intrathoracic tumor is of any considerable size, there will always be the danger of difficulty in making the tumor pass through the upper thoracic strait, thus producing pressure upon the trachea and, without an intratracheal catheter, causing the danger of suffocation.

It should be borne in mind in dealing with the tracheal obstruction in intrathoracic goiter that the performance of tracheotomy is extremely undesirable.

With the tube in place, any amount of manipulation and pulling, hauling and prying of the mass out of the mediastinum can be undertaken without danger of interfering with the respiration.

Total Thyroidectomy for Heart Disease

Total ablation of the thyroid for heart disease has been developed since 1932. According to Berlin, only those patients should be selected for this operation who, despite all available medical measures, continue to remain chronic invalids. In general, patients with slowly progressive heart disease who continue to suffer recurrent attacks of cardiac failure on exertion over a prolonged period of time will probably respond to the operation favorably, but those showing a short and rapidly progressive course should not be subjected to it. The operation is contraindicated also in the presence of severe impairment of renal function, acute pulmonary infection, or active rheumatic infection. The same consideration of the rapidity of the course of the condition should govern the selection of cases of angina. If the patient's history shows a rapid increase in the number of attacks, thyroidectomy will probably not give lasting results. When the metabolism is minus 15 per cent, operation should not be recommended. Of Berlin's patients with angina pectoris or congestive failure who were operated upon from one to two and one-half years ago, approxmiately 70 per cent showed marked or moderate improvement following the total ablation of the thyroid gland. In the last sixty-two cases there was no operative mortality. Berlin called attention to the danger of bilateral injury of the recurrent laryngeal nerve and advised laryngoscopic examination after the ablation of one lobe.

X-ray Treatment of Hyperthyroidism

Roentgen therapy has frequently been suggested in the treatment of hyperthyroidism. While it is admitted that in a large number of cases treated by x-ray there is a gradual improvement of the patient, radiotherapeutic methods have several serious drawbacks. The dosage is difficult to determine. The favorable result in the beginning may, due to the cumulative action of the x-rays, eventually prove to be excessive. This treatment has none of the precision of the operative treatment. It cannot conceivably be of any benefit in toxic adenoma. Arnold Jackson states that in the cases he has observed that have been treated with x-ray, the goiter has not been cured but the basal metabolism rate has been merely decreased so that the patient continues to run a low-grade hyperthyroidism. As a result of this the myocardium gradually becomes damaged and permanent injury results. He has seen a great many failures from x-ray therapy, and also a large number of cases with burns of the skin. Means and others have expressed similar opinions.

deQuervain asserts that radiotherapy is contraindicated in those cases of goiter which sooner or later come to operation. He states that inherent difficulties of an operation for exophthalmic goiter are increased to such an extent by x-ray as to almost render the operation impossible and that the adhesions after x-ray treatment are only to be compared in many cases to those produced by a previous thyroidectomy and usually they are more marked.

deJ. Pemberton in discussing the employment of irradiation in the treatment of exophthalmic goiter states that "it is based on the conception that the hypertrophic parenchymatous cells of the thyroid gland, as well as the lymphocytic infiltration commonly associated with the histologic changes found in this disease, are peculiarly radiosensitive, while the normal cells are peculiarly radioresistant. The functional activity can thereby be diminished without destruction of structure. Experimental proof is lacking that involutional changes occur in the thyroid gland of exophthalmic goiter after irradiation, for the difficulties of obtaining specimens from patients with exophthalmic goiter before and after irradiation are obvious. However, in a series of 4,061 patients with exophthalmic goiter operated on in The Mayo Clinic in 1926 to 1928, inclusive, the records show that 291 (5 per cent) had had previous treatment with irradiation. At operation only occasionally could the surgeon recognize any gross changes in the gland itself to indicate that it had been iradiated, and Broders was unable from miscroscopic study to distinguish that irradiated tissue from tissue that had not been irradiated." He further states that "after recognition of the value of iodine in reducing the operative mortality among patients with exophthalmic goiter, a paper was published by all the members of the committee of the Massachusetts General Hospital in which they compared the results of irradiation with those of surgery, and concluded that iodization followed by subtotal thyroidectomy is the best treatment of exophthalmic goiter. It is significant that the conclusion reached by this group of internists, surgeons and radiologists, namely, that surgery offers the best results in the treatment of exophthalmic goiter, tallies with the conclusions of similar groups of observers who have had wide experience in the care of patients with this disease. In The Mayo Clinic, irradiation has been employed in selected cases of exophthalmic goiter. In a small proportion of the cases, improvement has followed treatment, whereas in the others no change in the severity of the hyperthyroidism could be detected. Since the administration of iodine has proved superior as a preoperative preparatory method, irradiation has not been used in recent years except occasionally in a very small group of cases refractory to iodine. In these, the results have not been encouraging."

Personally, I believe that x-ray treatment is indicated in a certain small group of cases with hyperthyroidism when this treatment is administered by properly trained roentgenolists.

Discussion

Dr. L. H. Fowler: We are indebted to Dr. Nordland for a very interesting and complete survey of some of the important surgical conditions of the neck. There are several points worthy of discussion but in view of the length of the program, I feel that we should proceed with the other papers of the evening.

PRESENT STATUS AND MODERN ADVANCES IN THE SURGERY OF THE CHEST

Thomas J. Kinsella, M.D.
Minneapolis

Chest surgery is the youngest but at the same time probably the oldest special division of surgery. It is the youngest in its marked recent development but oldest by historical record for any of you who happen to be familiar with the Good Book may remember where it says "The Lord cast a deep sleep over Adam" and then the resection of the rib followed.

The modern developments in thoracic surgery have come about for three principal reasons: (1) improved diagnosis in the various conditions within the chest; (2) improved knowledge of the physiology of the chest, not so much from the standpoint of the physiologist as appreciation of it by the surgeon; (3) improvement in anesthesia and anesthetic technique and the use of oxygen therapy which has made many things possible in chest surgery.

Among the improvements in diagnosis which have come about in the last ten years or so, I think one should be mentioned specifically. It is an improvement in x-ray technic, in the use of the tomograph or laminograph through which it is possible to make films as serial sections a centimeter or two in thickness for the localization of abscesses, foreign bodies and various other lesions. They have been of great value and they will be of more value as time goes on. The method is not in common as yet but it is not a difficult matter to construct the apparatus and it will help us considerably in our diagnoses.

"Another thing which has helped is bronchoscopic examination and bronchoscopic treatments in thoracic lesions. Many of the conditions that we see in chest surgery now are better understood because of the knowledge which has been contributed through bronchoscopy, yet even today bronchoscopic examinations are not performed nearly as frequently as they should be. Esophagoscopic examination is also of value but likewise is not used as much as it should be. Another step in diagnosis which is neglected very often is the aspiration of fluid from the chest and replacement with air to permit better x-ray visualization of the thoracic organs and diagnosis and localization of various lesions in the chest. Careful microscopic study of aspirated fluid may help greatly in diagnosis.

Another neglected diagnostic procedure is the use of the thorascope. Where the lung is already collapsed by air or fluid is withdrawn and replaced with air a telescope or thorascope may be introduced and the interior of the thorax visualized very clearly. An accurate diagnosis may at times be made or biopsy specimens may be taken. This will eliminate a considerable number of exploratory thoracotomies, and is something that should be used more widely.

A number of years ago intrathoracic operations were somewhat of an ordeal. Under nitrous oxide anesthesia for open thoracotomy, fifteen to thirty minutes was about as much as any patient could stand, and the operation was a struggle for the patient as well as for the surgeon. Now, with modern anesthesia, it is possible to open the chest widely and leave it open for an almost indefinite period of time for surgical procedures and still keep the patient in good general condition. The use of the pressure cabinet which was used years ago when the chest was opened, has been abandoned and positive pressure anesthesia has taken its place. A knowledge of the effects of shifting mediastinum, movable chest wall, tension pneumothorax and sucking chest wounds, have all aided in our handling of thoracic conditions and helped us to treat these conditions much more safely than we could before such things were properly understood.

As far as anesthesia is concerned, I will leave that to Dr. Ralph Knight who really knows the subject. I merely follow along and try to work as he takes care of the patient.

Probably the first of the various phases of chest surgery that should be mentioned is the surgery of pulmonary tuberculosis. I mention this first not because I am interested in it primarily but because it constitutes such a large percentage of thoracic surgery today. Thoracoplasty, of course, is used much more widely now than it was a few years ago. All types of collapse therapy, in fact, are used more commonly. Ten years ago at Glen Lake only about 10 per cent of the patients discharged from the Sanatorium had been treated by any type of collapse while in 1937 53 per cent of the patients discharged had been so treated. This is just an indication of the increase in the use of such procedures. Thoracoplasty, of course, is not a new operation and there are probably more varieties than there are kinds of Heinz pickles. There are many special methods. Personally, I think that you should fit your survery to your patient, fit the type of operation to what the patient needs and can tolerate rather than to follow any special routine. One of the variations in thoracoplasty which has been developed in the last few years is the so-called Semb operation or an extra-fascial apicolysis in which, in addition to thoracoplasty, there is added a dissection of the dome of the pleura from the bands of Sibson's fascia, Sibeleau or Zuckerkandl bands, to allow the lung to collapse not only in a lateral and antero-posterior direction but also in a vertical direction. I believe there are some advantages to this procedure, but I don't think it is something to use as a routine. Probably 25 per cent of patients as we see them need something of the sort, but a number of those who need it can't have it because everything is bound down too much. If it is used as a routine, of course, you will have a great many good results but about 75 per cent of the patients do not need this added collapse.

Apical stripping, true apicolysis or extrapleural stripping combined with thoracoplasty is of value. There are some disadvantages there which are not generally appreciated, largely the danger of contamination with tubercle bacilli from tearing into tuberculous tissue as well as the danger of injury to the brachial plexus, the large veins in the apex, injury to the sympathetic, etc.

The past ten years have seen the rise and fall of two types of thoracic surgery. One is phrenic nerve surgery about which many men became so enthusiastic that there were reports made of a series of several thousand performed within a few years. It was then done almost as a routine. Now it has fallen largely into disrepute. I believe that it has a definite field though it is much smaller than was originally anticipated. The same thing may be said of section of the scalene muscles to allow relaxation of the upper portion of the chest. It was used rather extensively for a while but now it is almost abandoned.

Pneumothorax, of course, is used much more widely than previously. Bilateral pneumothorax is now a common procedure whereas ten years ago it was somewhat of a rarity. It is started, of course, much earlier than it used to be. Oleothorax, that is, the substitution of an oil filling for the air pocket in pneumothorax has a definite field, particularly in patients who have to be sent out into outlying districts where they can't obtain air refills. There are certain disadvantages to it but I think it has a small field in the treatment of tuberculosis.

A new procedure which has been introduced in the last year or two, that is, extra-pleural pneumothorax, will, I believe, probably have a small field. At the present time many men are as enthusiastic about it as they were about phrenic nerve surgery a few years ago and undoubtedly will overdo it. It is used in patients who have an obliterated pleural cavity so they cannot take an ordinary artificial pneumothorax and who are not suitable for thoracoplasty. A piece of rib is resected posteriorly and parietal pleura stripped from the inside of the chest wall, apex and upper mediastinum. The wound is then sutured, leaving the space filled with saline which is aspirated in a day or so after the wound is sealed, and replaced with air. The collapse is maintained by extrapleural injections of air under positive pressure from that time on. Certain patients who are desperately ill, have large cavities, and are not good subjects for thoracoplasty or other radical surgery, may be helped by this method. It is very much an institutional type of procedure, and at the present time there are very few places where a patient can be sent out of a sanatorium and still be carried on such a procedure. Extrapleural oleothorax may be the answer to this problem.

Extrapleural paraffin "Plombe" which is not new, I believe, has received added interest in the last few years. We have had a series of approximately one hundred patients with some very nice results. It is not altogether fool-proof but there is a place for it.

Pneumo-peritoneum is another procedure which has been added to our therapeutic measures in pulmonary tuberculosis. Air is injected into the peritoneal cavity with the idea of pushing the diaphragm up, immobilizing the lung and obtaining some improvement by this immobilization. With pneumo-peritoneum it is perfectly possible to push the diaphragm up to the third rib on each side. The patient may become short of breath, or have difficulty with the gastro-intestinal tract for the stomach is collapsed by the pressure that is used. So far, I am not convinced that it has helped a great many patients. It is something to use where you cannot use anything else, and in that way may be worth while.

In general, I would say that the most important change in collapse therapy has been its wider use and earlier use. It has given us better results because the patients were in such condition that they could expect more because they had not become depleted by prolonged or extensive disease.

The field of empyema has shown little change in the last ten years. A number of trick methods of treating empyema have been introduced but they are usually fads and have not changed the field appreciably.

In the treatment of lung abscess, the old standard, two-stage external drainage is still good. Lobectomies, however, are being considered more frequently and are being used occasionally for the treatment of special cases. We have a man down at the General Hospital now in whom lobectomy was done in preference to an external drainage because of repeated profuse pulmonary hemorrhage, where we feared that he might bleed to death from the lung while we were waiting for the pleura to become adherent before the second stage. It has worked out very nicely. Bronchoscopic aspiration and localization has been of value. A considerable number of lung abscesses can be treated bronchoscopically and good results can be obtained in this way without external drainage. The whole thing is, if results are obtained in two or three treatments through the bronchoscope and adequate drainage established, all well and good. If results are not obtained within two or three treatments, then it is time to stop and do something else. There is no necessity for carrying it on for months.

The surgical treatment of bronchiectasis has received increased attention in the recent years. The Graham cautery is not used as much as previously, though I believe it still has a field in the treatment of bronchiectasis complicating pulmonary tuberculosis.

Lobectomy and pneumonectomy have been used rather widely and some excellent results obtained. The results of lobectomy have improved while the mortality has dropped from the 40 per cent of a few years ago to around 2 to 4 per cent in certain series. Pneumonectomy is still a procedure of considerable magnitude and carries a considerable risk. It is, however, justifiable in some of these patients.

Carcinoma of the lung is one condition which was untouched a few years ago but is now treated by thoracic surgery. The first case of carcinoma of the lung successfully treated by pneumonectomy was by Graham in 1933. Early diagnosis, of course, is essential. We must suspect carcinoma of the lung and look for it, bronchoscope the patient and use iodized oil or we will never find it in an operable stage. Even today about nine cases out of ten that you see have progressed too far for successful surgical treatment when the diagnosis is made. Pneumonectomy is the surgical procedure of choice as it gives a chance to remove the regional nodes as well as the whole of the involved lung. It still probably carries a mortality of about 25 per cent, depending upon local conditions but as we have nothing else to offer in carcinoma of the lung I believe the risk is justified.

Benign tumors of the lung, adenomas, etc., have been recognized in increasing numbers in the past few years and successfully treated through the bronchoscope. A considerable number of these have probably been treated by diathermy, x-ray and other means within the past ten years and reported as carcinomas of the lung and good results obtained.

The other fields in thoracic surgery have not changed particularly. There have been procedures developed for drainage of mediastinal abscesses, but it is still a very desperate condition. Mediastinal tumors have been successfully removed by modern thoracic surgery under intratracheal anesthesia. The esophagus may now be resected. There have been a number of cases in which the Thorek operation, for complete removal of the esophagus with an external communication established through a rubber tube, have been reported. A few of these have come out rather well.

Cardiac surgery has shown a few improvements but nothing startling. A number of cardiac wounds have been successfully sutured. The effects of cardiac tamponade have been recognized and the importance of its relief stressed. Pericariolysis by the Brauer operation of taking out the overlying ribs and cartilages or the more radical removal of the calcified pericardium, has been used from time to time. It is still a procedure which offers something but is not of too great value.

Two procedures have been introduced in cardiac surgery with the idea of establishing increased blood supply to the myocardium in patients with angina. In the Beck operation the pectoral muscles are transplanted into the pericardium as a pedicle flap to form adhesions and give increased blood supply. Some nice results have been reported but they have all been done on early cases, and the late results are not yet available. The O'Shaughnessy operation in which the pericardium and the diaphragm are both opened and the omentum pulled up and sutured in the pericardium to form adhesions is an accessory of the same type. The Trendelenburg embolectomy for removal of pulmonary emboli has been used a number of times, but the whole difficulty seems to lie in diagnosing what patients need it. It is probable that a considerable number of patients who have recovered might have recovered without operation. It probably never will have a very wide field of usefulness.

ANESTHESIA IN CHEST SURGERY

Ralph Knight, M.D.
Minneapolis

Even in thoracic surgery there is a considerable choice of anesthesia methods.

For thoracoplasties of not too great an extent, such as those required in the treatment of empyema cavities, and even for the removal of several ribs, especially the lower ones, in the treatment of tuberculosis, paravertebral anesthesia is always to be considered. To accomplish this 10 c.c. or a little more of a 1 per cent solution of procaine, or metycaine, is deposited just below the tip of the transverse process of each vertebra of the segments involved. With rather slow and careful surgery, to avoid too great tugging and jarring of the patient, extensive resection and even disarticulation of ribs can be accomplished.

Peridural anesthesia is another form of regional anesthesia which is sure to be further developed in chest surgery.

One must not forget that spinal anesthesia has, in many hands, an extensive field in chest surgery. It must be administered with a special technic. A weak solution of procaine must be used because a large volume is required and because one must count upon obtaining sensory anesthesia without motor paralysis. Procaine is the drug of choice because anesthetic doses of others tend to produce more motor paralysis. From 10 c.c. to as much as 15 c.c. of a 2 per cent solution is injected intradurally in the lumbar region. If properly done, satisfactory anesthesia is obtained and the patient can breath and cough as directed by the surgeon. Any type of operation upon the chest wall and even lobectomy can be performed, some surgeons preferring spinal anesthesia above all others for lobectomy. I know of none who is using it for pneumonectomy and I believe it would be impractical.

For limited thoracoplasties some chest surgeons are employing intravenous anesthesia. Although I am very fond of intravenous anesthesia for many purposes I feel that it is not quite suitable for this. The patient is usually on his side and the lower arm is usually compressed at the axilla, interfering with free venous flow. The upper arm is subject to sudden movements with the work of rib resection. This makes it almost impossible to administer the anesthetic into either arm smoothly and certainly enough. If one attempts to use a foot vein he is too far away for good observation of the signs of anesthesia. Another disadvantage is still more important. During operations upon the chest one must have definite control over respiration. In intravenous anesthesia respiration is apt to be greatly subdued and there are no adequate means of control such as accompany local or inhalation methods.

Inhalation anesthesia offers certain advantages over all other types for chest surgery. As Dr. Kinsella suggested, time is unlimited and respiration is under absolute control by the anesthetist. The patient is, of course, unable to cough out secretions as he can do under spinal and local anesthesia but the anesthetist can keep the bronchi clear by aspiration. In order that lung movement and ventilation can be perfectly controlled and secretions cleared away, inhalation anesthesia for all chest surgery, except quite limited procedures upon the chest wall, should be administered through an intratracheal tube. At the University Hospital for several months we have introduced all intratracheal tubes under intravenous anesthesia, thus saving the patient and anesthetist a long gas-ether induction.

We have found this very satisfactory from all standpoints. Anesthesia is then maintained by inhalation through the tube. There has been some general discussion, of course, regarding the propriety of introducing a tube into the trachea in cases of tuberculosis, the fear being that the irritation might tend to light up an infectious process. The obvious advantages are much greater than any theoretical disadvantages and have been generally recognized as such. With this technic, anesthesia can be safely conducted and operation carried on, even with the chest open, for a longer period of time than in almost any other type of surgical procedure. Cyclopropane is the inhalation anesthetic of choice for this work. There are no others which compare with it in value for chest surgery. The advantage of high oxygen and ability to carry the anesthesia with quick changes from light to deep and deep to light according to the needs of the situation are all there and all should be taken advantage of. At the close of the anesthetic a thorough "tracheo-bronchial toilet" should be carried out by aspiration with a catheter through the tracheal tube and the anesthetist should then inflate the lungs with air to replace the rapidly absorbable oxygen and anesthetic gas. The bag should be emptied and refilled with air several times and bag-pressure of 12 mm. mercury applied intermittently during each inspiration. The aspiration and air inflation are the best safeguards against the danger of atelectasis.

PRESENT STATUS OF GALLBLADDER SURGERY

A. A. Zierold, M.D.
Minneapolis

During the past ten years, a tremendous volume of literature has been published concerning the gallbladder and the biliary tract. A relatively small amount of this has dealt with the surgery of this region, but notwithstanding, a sufficient discussion has developed to establish some definite departures from the previously accepted doctrines.

Largely through the efforts of Andrews and his associates, the concept of gallbladder disease under the term "cholecystitis" has been subjected to careful inquiry.

A review of the published experimental and clinical investigations fails to disclose sufficient evidence to state that cholecystitis is bacterial in origin. The status of the theory may be summarized as follows:

1. Bacteria are seldom found in the gallbladder wall or content.
2. Microscopic studies are not characteristic of bacterial invasion elsewhere.
3. Experimental cholecystitis cannot be produced except occasionally by overwhelming doses of bacteria.

On the contrary, the characteristic changes of cholecystitis can be produced by chemicals and foreign bodies. The evidence at the present time seems to indicate that cholecystitis is not primarily a bacterial disease.

That this conclusion is generally accepted may be inferred by the infrequent mention of the gallbladder as a focus of infection and the abandoning of the idea that it is a sequel to appendicitis or a forerunner of pancreatitis or peptic ulcer.

Further corroboration is to be found in the work done relative to the formation of gallstones. Boyden's demonstration of bile stasis in pregnancy and the investigation of Abrahamson, Neumann, Walsh and others show beyond reasonable doubt that infection is quite unnecessary or at most incidental in the development of cholelithiasis.

As a result of this changing concept of gallbladder disease and also as the result of more careful postoperative surveys, the prevailing opinion amongst surgeons here and abroad is that operations upon the gallbladder are rarely necessary unless stones are present.

Lahey contends that every patient having stones in the gallbladder with or without symptoms should be subjected to cholecystectomy on the grounds that in so doing the incidence of common duct stone will be lowered. Opposed to this extreme view are Andrews, Foss, Graham, Stanton and others who feel that only the stone-bearing gallbladder which gives definite symptoms should be a candidate for operation, and cite a mortality of 1 per cent in all untreated cholelithiasis in the registration area.

Lahey also maintains that of the cases coming to operation for gallbladder disease, 50 per cent will require exploration of the common duct. The reports of Best, Pool, Sweet and others tend to support this belief, but this by no means represents a majority opinion.

A compromise, however, appears to be developing through the more general use of the cholangiogram. In 1932 Mirizzi suggested cholangiography with lipiodol, and in 1936 Robbins and Hermanson proposed the use of hippuran. Since this time, the procedure has been popularized by Walters, Mixter, Best and many others. At the present time, the prevailing practice may be summarized as follows:

When a patient is operated upon for gallbladder disease, the common duct for at least a short distance is exposed and examined. If it is found to be dilated, one of two courses may be followed. The bile may be aspirated by needle and examined. If abnormal in any respect, the common duct is then opened, explored and drained. An alternate procedure is to inject a radiopaque substance directly into the common duct either through a sectioned cystic duct or through the common duct wall by means of a needle and obtain a cholangiogram at the operating table. This technic appears to be the more popular not only in identifying common duct stone or obstruction preliminary to choledochotomy, but for the purpose of demonstrating residual stones after operation.

Paralleling the development of cholangiography and on the basis of investigations by Boyden, Ivy, Westphal and other physiologists, is the rise of a considerable interest in the so-called choledochus sphincter dyskinesia. It has been shown that spasm of the sphincter of Oddi may not only be of sufficient degree to cause pain, but also to the point where reflux jaundice and liver damage occur.

Walters and others have shown that such spasm may be responsible for the occasional colic following cholecystectomy or choledochotomy. It has also been shown that sphincter spasm is relieved by nitrites but augmented by morphine.

Best puts this phenomenon to further use in an attempt to flush out the biliary tract by first employing desoxycholic acid to raise the intra-ductal pressure and then suddenly releasing it by the administration of nitrites. Colp has devised an instrument for intraductal section of the sphincter, while Bakes, Allen and others prefer forcible dilatation with bougies. These technics, while simple in conception, are not so simple in practice, and as yet are not in common use.

It would appear from the knowledge gained thus far that cholangiography is a valuable, safe adjunct to surgery and that preliminary investigation of the sphincter mechanism may help to differentiate gall bladder disease from sphincter or common duct derangement.

The case for acute cholecystitis must be considered quite apart from all else, as it is still a battle ground for surgeon, pathologist, physiologist and anatomist. While it is true that the concept of acute cholecystitis is changing, there is at present insufficient evidence, clinical or experimental, to identify it as a bacterial, chemical or foreign body reaction. The modern trend of treatment appears to be based more upon the clinical behavior of the organ than upon its pathologic picture. Bergh's recent review of the literature illustrates very well the existing confusion.

The most that can be said is that acute cholecystitis is being treated by competent surgeons in one of three ways: (1) immediate cholecystectomy; (2) early cholecystectomy; (3) late or interval cholecystectomy. The published mortality tables are not sufficiently comprehensive to validate any one procedure to the exclusion of others.

In all the foregoing phases of biliary tract disease, jaundice is a not infrequent complication. It is not within the scope of this discussion to consider this phenomenon except as it affects surgical practice. The prolonged bleeding time in the severe grades of jaundice has recently been investigated with some gratifying results. Ivy, Ravdin, Greene, Snell and others have demonstrated conclusively that calcium deficiency has no relation to the bleeding tendency. Following Quick's discovery of a method for determining prothrombin, Almquist and Stockstad in this country and Dam and Schonheyder in Denmark identified prothrombin alteration with vitamin K deficiency. Ivy also found that the prothrombin level could be restored by large doses of viosterol. As a result of this work, the hemorrhagic tendency of jaundice has been brought under control and the fear of post-operative bleeding is no longer a deterrent to surgery. To measure bleeding time more accurately and provide a better index of operability, Ivy devised a method which to the present date is satisfactory for both clinical and experimental purposes.

In summarizing this brief review, little remains except to emphasize the slow but apparent change in the concept of gallbladder disease, and the importance of the duct sphincter mechanism as demonstrated by newer methods of study.

Discussion

Dr. E. A. Regnier: The essayists this evening have made their papers so inclusive that very little is left to be said on the subject. The impression that one gathers after listening to Dr. Zierold's presentation is that we have about as much latitude in gallbladder surgery today as we had twenty-five years ago. Many phases of the subject are still rather controversial, hence every case must be individualized.

One phase of gallbladder disease, namely acute cholecystitis, must be brought to your close attention. We must keep in mind that acute cholecystitis in the first twenty-four to thirty-six hours of its development is not an acute suppurative process. Sections made from these tissues show few if any bacteria in the gallbladder wall; likewise, few bacteria in the contents of the gallbladder. It is generally recognized that the first stage of this inflammatory process follows obstruction of the cystic duct. After thirty-six hours, or thereabouts, an acute suppurative process usually develops and subsequently there is a certain amount of hepatitis adjacent to the gallbladder.

Some men looked upon the early changes in acute cholecystitis is an allergic phenomenon. I believe that this is a new avenue of approach to common-duct surgery.

The jaundiced patient, together with the variations and alternations in the bleeding and clotting time of blood in these patients is a problem that can be best met or solved by the use of frequent blood transfusions to replenish the prothrombin in the blood stream. When synthetic vitamin K is generally available its use may obviate the necessity of blood transfusion.

RECENT ADVANCES IN SURGERY OF THE ABDOMEN AND ABDOMINAL WALL

Stanley R. Maxeiner, M.D.

Minneapolis

I have tried to go over some of the more recent reports of subjects that have been particularly interesting to me and it is quite obvious that it is impossible to cover everything that has been brought out in the literature.

The first thing that I have chosen to speak about is disruption of the abdominal wall, which is one of the ever-present worries of the general surgeon. It is of universal concern because it occurs in every general service in every hospital. It occurs unexpectedly and carries with it a very high mortality.

Grace[1] reports thirty-six cases with protrusions of the abdominal viscera and ten without protrusion of the viscera. It occurs at all ages from very young infants to the very aged. An analysis of these cases showed:

	Cases
Split right rectus, upper	28
Split left rectus, upper	8
Median epigastric	3
Split rectus, lower	3
Reversed Kammerer	2
Transverse	1
Median suprapubic	1
Total	46

Thirty-nine of the forty-six disruptions occurred in upper abdominal incisions. In their cases the majority of eviscerations occurred following operations for carcinoma, chronic ulcer, gallbladder disease and appendicitis. This suggests, at least, delayed healing in debilitated, run down individuals. Indirect causes listed by Grace were as follows:

	Cases
Infection	17
Coughing (pneumonia, 5 cases)	17
Vomiting	9
Distention or obstruction	4
Hiccoughing	4
Retching at lavage	2
Difficult sew-up	2
Patient getting out of bed	3
Not known	3

Infection, coughing, vomiting and distention were postoperative complications which occurred in forty-seven of their cases. Disruption may occur any time from the second to the fourteenth day or even later, but the majority of their series occurred between the fifth and tenth days.

Pink staining of the dressings accompanied by a watery discharge of peritoneal fluid may be one of the earliest symptoms, and as separation progresses, evisceration occurs. Secondary suture was employed in thirty cases and packing or strapping in sixteen. Where protrusion of the abdominal viscera occurred, the mortality was 41 per cent, but where evisceration did not occur, the mortality was 30 per cent.

William Crawford White[4] states that they have had no eviscerations in the intramuscular, Pfannenstiel or transverse incisions but disruption is essentially confined to midline, split rectus and the laterally retracted rectus incisions. In their series of eviscerations the mortality was 53 per cent. He believes there is a definite failure of healing in the aged, the decrepit, the malignant and the jaundiced due to inanition. He finds cough, distention and infection to be definite exciting causes but likewise believes that early absorption of catgut is an extremely important factor. Debilitated patients are being closed by through-and-through silk sutures put closely together and their disrupted wounds are being closed by the same method.

Isidor Kross,[3] in a review of 4,433 operations at Beth Israel Hospital, found occurrence of eviscerations to be just over 1 per cent. Sex and age were of no importance. He states that the theories generally advanced are: (1) failure of the suture material; (2) unusual strains; (3) constitutional factors and debility causing a failure of the wound healing processes; and (4) wound infection. He refers to the studies of wound healing made by Meleny and Howes, who divide the healing process into two stages: (1) the exudative, which lasts four or five days; and (2) the reparative stage, beginning at the end of the first stage and continuing until wound healing is complete.

In the first period an exudate develops which depends upon the number of injured cells, the amount of extravasated blood and lymph, bacteria in the wound and the amount of suture material employed. During this period the tensile strength of catgut sutures diminishes rapidly. As the exudate undergoes absorption, fibroplasia takes place with the formation of new scar tissue and a progressive increase in the strength of the wound. Tissue necrosis, hemorrhage, infection and debility delay the reparative processes. Freeman and King believe that an incomplete closure of the peritoneum permits a bulging of omentum or loop of intestine which, acting as a wedge, forces the tissues apart and eventually breaks through the skin. This factor is supported by the appearance of the edges of eviscerated wounds inasmuch as only the most recent part to separate is found to be bleeding. The other surfaces are gray, covered with exudate and do not present the appearance of being freshly torn apart.

Dr. Ralph Knight,[2] of our own Society, referred to reports by Sokolov, Willard Bartlett, Max Thorek and others, and reported four interesting cases of his own.

Practically all writers agree that catgut is not to be depended upon, that during the exudative period it rapidly decreases in strength and, in many individuals, absorbs before healing has taken place. The literature abounds in case reports in which, at the time of resuture of disrupted wounds, catgut with no tensile strength is found in the tissues.

William Hinton suggests allergy for an explanation of wound separation and incisional hernia. Decline in the strength of catgut after exposure to living tissue has been investigated by Rhoads. Implantation of several makes in the abdominal walls of dogs showed that the tannic iodized type presents substantially more resistance to tissue fluids than medium hard chromic catgut and is less acted upon by infection.

Fallis of the Henry Ford Hospital reports fifty disruptions to have occurred in 7,903 laparotomies. They perform immediate secondary closure with a mortality of 34 per cent.

From the foregoing it is obvious that wounds disrupt after closure with any type of suture. However, practically all essayists agree that catgut alone is not reliable. Even when tension sutures are used they may cut through the tissue and permit evisceration. However, if there is any lesson to be gained from the above it must be that in certain groups of cases where wound security is questionable one should exert every possible effort to prevent this dire complication.

A great deal of study has been going on in the last few years relative to the development of new and better sutures. C. J. Kraissl recommends some way of dispensing catgut other than the narrow glass tubes, which he believes kinks and weakens the strands. He also believes that during the absorption of the protein in catgut, the metals and halogens it contains are liberated and cause irritation which may interfere with wound healing. He believes this is particularly true of chromium, to which certain individuals may be sensitive. He states that it is possible to sensitize guinea pigs to catgut so as to produce disruptions in laparotomies sutured with this material. He also says, "The highest incidence of sensitivity was a group in which wound disruption had occurred and all allergic patients who had disrupted exhibited a sensitivity to one or more antigens." He suggests preoperative testing of individuals by appropriate skin tests before using catgut for abdominal closure.

Shambaugh and Dunphy state that postoperative infection in contaminated wounds occurs less frequently when fine silk is employed. They believe that silk is much less irritating. They also used contaminated catgut and silk to close wounds in experimental animals. Their conclusions were that wounds thus infected healed better with silk than with catgut.

We have all experienced slowly healing sinuses in abdominal incisions which healed rapidly after the removal of a chromic knot. The essayist, twenty-five years ago, went through the stage of nonabsorbable suture, at which time it was necessary to use fine fish line in order to get silk with adequate tensile strength. Silver wire filigree was often used to reinforce incisional defects but in most instances these gross foreign bodies had to be removed.

Clifford Collins and J. Bellas, in a paper to be presented before the Western Surgical Association in December, state, "The ideal suture must be one that is non-reacting, one that is not affected by the enzymatic, chemical, physiologic, bacteriologic and physical influences such as occur in the body tissues and hence one that does not interfere with prompt, normal repair. Such an accomplishment is believed to have been attained in a new suture called platisgut on the basis of extensive animal and clinical experience."

Regarding carbon dioxide inhalation during closure of the abdomen, it would appear that there is still considerable controversy concerning its value. Thomas Ryan, Philadelphia, states, "It would appear that carbon dioxide is of no value in prevention of postoperative pneumonia." This is based on two series of patients in which 2.2 per cent of pulmonary complications developed following the use of carbon dioxide and 1.4 per cent complications in a similar group of cases where carbon dioxide gas was not used. These statements, however, are not conclusive and undoubtedly will not check with the findings of many others.

Roscoe Graham points out, "The surgeons' responsibility in the treatment of duodenal ulcer is to patients suffering from complicated ulcer, penetration, obstruction, recurrent hemorrhage or perforation." Treatment must result in the absence or decrease of free hydrochloric acid in the gastric contents. Gastroenterostomy should be reserved for scar stenosis and low free hydrochloric acid, and for elderly patients with penetrating nonobstructing ulcers but with low free hydrochloric acid in the gastric contents. All other patients should be treated with radical subtotal gastrectomy. In the treatment of acute perforation in duodenal ulcer, simple closure is all that is indicated.

Leon Goldman states that the mortality from bleeding ulcer is much higher than previously supposed. Repeated hemorrhage shows a rising mortality and surgery should be considered in view of intractable medical treatment.

Graham, Kalk, Strauss, Berg and others indicate a definite swing to the more radical gastrectomy. The Billroth I type of resection does not lend itself to the same successful results as the more radical Billroth II or the Polya type of resection.

Smith and d'Abreu of London recommend the anterior incision of the duodenum and suture of the posterior duodenal ulcer to control hemorrhage, while Hans Finsterer of Vienna is strong for the more radical type of operation. Finsterer states that when operation can be performed at the onset of hemorrhage or at least within twenty-four to forty-eight hours, satisfactory results can be expected with a very low mortality. On the other hand, the results of late operation for hemorrhage are bad, having had sixteen deaths in fifty-three resections. In forty-four resections following chronic hemorrhage, there were but two deaths.

While Berg and Strauss claim a larger percentage of marginal ulcers following gastro-enterostomy, the results claimed by the Mayo Clinic are much lower and gastro-enterostomy still has its definite indications.

Still states that of 105 patients on whom partial gastrectomy was performed for gastric ulcer, 103 were able to do hard work without restrictions of diet, and of 236 resections for duodenal ulcer, 223 were cured. Following 292 gastric resections there was only one gastrojejunal ulcer.

Lake reports 65 partial gastrectomies with immediate mortality of 6.3 per cent with 89.8 per cent satisfactory results. Berg, from the Mount Sinai Hospital, records 401 primary resections for gastric and duodenal ulcers with mortality of 6.9 per cent. Among 516 cases of primary and secondary gastrectomy he reports only six cases of possible recurrence, an incidence of 1.1 per cent.

Jennings reported a new and successful method of total gastrectomy in which the jejunum is sutured to the diaphragm and the ligated, cut-off end of the esophagus, which is free from the peritoneum, is introduced through the wall of the jejunum so that healing takes place between the jejunum and the diaphragm. Dr. Wangensteen of our Society has proposed a similar new technic for total gastrectomy performed in two stages.

H. B. Sprung reports the end-results of 464 resections of the stomach for cancer. The mortality in the aged was 31 per cent while only 4 per cent in young subjects. The majority of deaths were caused by peritonitis or pulmonary complications. Three hundred twenty-five lived over one year, 233 over five years and 102 over fifteen years.

Gatewood has repeatedly called attention to the fact that the poor results from resection of gastric cancer is in part due to the pessimistic attitude of the doctor who is frequently to blame for the fact that the average patient does not report to the surgeon for operation for months following his first diagnosis of carcinoma.

I wish only to call attention to the work of Best and Hicken on the treatment of stones remaining in the common duct following surgery. Irrigation of the common duct through a T-tube with ether and alcohol, normal salt solution and oils, together with the use of antispasmodics such as atropin, glyceryl trinitrate, etc., will frequently empty the common duct of its remaining stones. A recent case of our own treated by this technic has responded readily with rapid emptying of the common duct as shown by visualization through the use of opaque media.

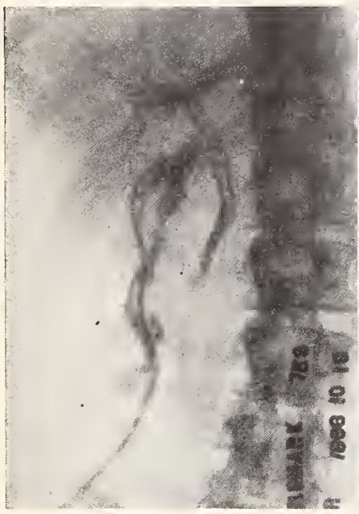

Fig. 1.

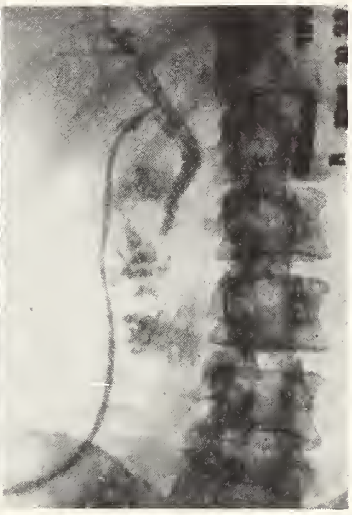

Fig. 2.

Fig. 1. Injection of the T-tube in the common duct with diodrast, six days post-operative. The ampulla is completely closed. The arrows mark negative shadows interpreted as small stones but which we believe to be air. Most of the injected solution follows out the sinus. The patient had gross symptoms of malaise, lack of appetite and general lack of well-being from the absence of bile, together with chalky stools.

Fig. 2. Through the T-tube the common duct was irrigated with ether, normal salt solution and oil, and the patient was given atropin, sedatives and glyceryl trinitrate for ten days. All drainage of bile around the tube stopped. Injection with diodrast showed the ampulla open and the dye passing directly into the duodenum. The T-tube was immediately removed without further biliary drainage after twenty-four hours.

The patient, aged forty-five, was operated upon for cholelithiasis. The gallbladder contained many small stones. The common duct was explored and found to contain numerous small stones and mud. A probe was passed through into the duodenum and the duct was thoroughly washed out with salt solution.

The operation which Lahey described before this Society for exteriorization of the right colon and anastomosis between the small bowel and transverse colon after the technic of Mikulicz is a great step forward and has greatly reduced the mortality and morbidity in handling carcinoma of the right colon. The double barrel colostomy of Lavine through which the distal colon may be irrigated and cleansed of infection will greatly reduce the mortality of resections of the distal colon, particularly for inflammatory disease such as diverticular tumor where the distal segment may be allowed to remain for a long time and to be almost completely sterilized. The similar operation as proposed by Lahey and Cotrell for sterilization of the rectum before the second stage resection has been extremely successful in our hands and I believe unquestionably will lower the mortality for radical resection for carcinoma of the rectum.

Rankin states that in the past three years he has found it advantageous in handling cancer of the rectum to adopt the following definite proposals.

1 He has abandoned intraperitoneal vaccination.
2 He has eliminated spinal as routine anesthesia.
3 He has extended preparation to at least seven days.
4 He has instituted routine presacral neurectomy.
5 He uses postoperative blood transfusions routinely.
6 He has adopted wider use of the single stage abdomino-perineal resection. Rankin concludes that there is no doubt but what there are cases in which it is advantageous to use the two-stage radical maneuver, and furthermore there are many cases in which it is unwise to employ either of these radical procedures in which operation may be undertaken by colostomy and posterior resection.

Gabriel of St. Mark's Hospital, London, reports an operative mortality of 7 per cent, which is almost identical with Rankin's 7.7 per cent. He also reports a 52 per cent five-year survival for all groups and all types combined.

With reference to Rankin's statement regarding presacral neurectomy we believe that this not too difficult procedure is a very definite step forward in the relief of chronic pelvic pain, especially that associated with certain types of malignancy. During the past year we had a patient complaining of almost intolerable pain in the pelvis following four pelvic laparotomies because of inflammatory disease of the tubes and cystic disease of the ovaries. In her last pelvic laparotomy performed by us, hysterectomy and presacral neurectomy were performed, following which the patient has had complete relief from pain.

Fallis reports 1,600 consecutive operations at the Henry Ford Hospital for hernia with a recurrence rate of 8.25 per cent, 7.4 per cent for indirect hernia and 11.6 per cent for direct hernia. They stress particularly in direct hernia, repair and reinforcement of Hesselbach's triangle. In the direct hernia it is important to repair the transversalis fascia. Bilateral operations show a definite increase in postoperative complications and in the recurrence rate. In the repair of direct hernias, large indirect hernias and recurrent hernias, together with large postoperative ventral hernias, the ordinary catgut closure is grossly inadequate and is followed by a large percentage of failure. In these patients we strongly advocate some more secure means of closure, such as the use of the McArthur strip in the inguinal hernia or the use of fascia lata after the technic of Gallie. With the more recent advances in sterilization and operating room technic and the vastly improved tensile strength of fine braided silk, we have personally experienced a very definite swing toward its substitution for catgut.

Dr. Culligan, a member of this Society, in a recent paper reported a 56 per cent reduction of recurrences in direct inguinal hernia by the use of some type of fascial suture. In most instances the McArthur technic was employed, paying particular attention to suture of the transversalis fascia.

We recently performed secondary cholecystectomy for recurrent empyema of the gallbladder with chronically infected sinus and postoperative incisional hernia. We were certain that, with extensive suppuration, catgut could not be relied upon and adopted the procedure of Babcock and others, of closing the abdominal wall with steel wire. Suppuration was marked as anticipated, the wound held securely and the wire has become firmly incorporated as evidenced by x-ray examination.

There has been a definite return of the Ochsner method in the treatment of late cases of appendicitis. I believe that this is a step forward and is due to the excellent teachings of Dr. Wangensteen as fostered at the University Hospital.

Intestinal decompression by continuous suction has become extremely popular. The modified Miller Abbott tube, which consists of two small tubes lying side by side through one of which a small balloon may be distended, aids the passage of the tube through the small intestine and intubates a much lower level. Many patients may be tided over without surgery and those with definite mechanical obstruction are often improved to the point that surgery is rendered much more safe.

Discussion

Dr. Arthur F. Bratrud: Dr. Maxeiner has covered so many phases of this subject so completely that it is practically impossible to add anything. However, there are a few things that might be mentioned, in regard to some of the newer advances in surgery. Dr. Maxeiner spoke about the plastic repair in hernias. In looking over the literature, you may have read a few articles where "cold water" is being thrown upon the plastic repair of hernias, that the recurrence rate is higher where plastic repair is performed than where it is not performed. I am going to read just a short statement that was made in 1890 by Halstead in referring to Dr. Bull and speaking of hernias at that time. Hernia surgery really began about 1880, and in 1890 here is the statement he made: "That ten years have elapsed since the modern radical operation for inguinal hernia has been in vogue, we ought to have presented to us patients who have been more than five years at the least without relapse. We could naturally expect to see such cases occasionally, but there are none such."

I think that may be the attitude a good many men are taking toward the newer advances in surgery, and especially toward plastic repair in hernias. I have had some interesting experience as far as fascial proliferation is concerned. Quite a number of years ago, in suppurative abdominal cases, I began closing these patients with just strips of adhesive tape. The peritoneum was sutured, but nothing else was sutured, and it is interesting to note what happened. Most of those patients healed by primary union in about two weeks. There was no suppuration in the wound or fascia with very little separation of fascia. Occasionally a patient would develop a hernia and I thought that by taking a forceps and clamping across the edge of the cut fascia so as to hold the edges together, without any suture but by leaving the clamps on for two days, that hernia could be prevented. What happened was this: Those wounds all became infected, due undoubtedly to the trauma produced by the clamping of the forceps across the fascia, and the fascia sloughed. With the patients who did not have the clamp put on, a very interesting fact was observed when they came to operation if a hernia had resulted. Instead of the fascia coming out to a point in a "v" shaped manner, being very thin at the margin, it was thick and round, a good deal like the shape of a pear, so that the closure of those hernias was very easy. All that was necessary to repair the hernia was to split the fascia, because there was so much proliferation and thickening of the fascia.

I think that brings up the very interesting observation as far as the plastic repair of hernia is concerned. Usually when we take the fascial strips, a clamp is fastened across the fascia before the stripper is put on. This does definitely traumatize the fascia and traumatized fascia is more liable to become infected. I think that we all make a mistake when we do not cut off that traumatized area before we attach the silk suture and attach the fascia in the wound, in plastic repair of hernia, because it undoubtedly is a predisposing factor toward inducing infection in that wound. Infection is one of the complaints of most of the men who have been doing fascial transplants. The high incidence of infection in these plastic repairs of hernia is undoubtedly the cause of the high recurrence that is being reported. Fascia properly handled and used in a transplant does remain viable and does not atrophy and absorb, as stated by some surgeons. While doing peripheral nerve surgery in the Army I had the opportunity to operate in cases where fat fascia transplants had been placed around the nerve suture line, as many as three years previously, and the fascia had not absorbed.

I have always been rather in favor of silk suture of wounds. I have made the statement at the hospital a number of times to the internes, that I would like to see ten patients in whom catgut is used and ten in whom silk is used. I could then send any interne down through a ward and he would be able to pick out the ten patients in whom silk had been used and the ten in whom catgut had been used. You can do that very easily because there is an induration and thickening in the tissues following the use of catgut, whereas with silk there is a very nice soft wound. Anybody can pick out the cases that have been operated upon with fine silk. That simply confirms the observation made by some men connected with the Chicago University in regard to wound healing, and also recently emphasized by Whipple (I believe one of the last articles was in Annals of Surgery), that you get more exudate in wounds where plain catgut is used than where you use chromic catgut. Chromic catgut produces more exudate in wounds than silk does. In other words, there is apparently some allergic factor in or irritation from the catgut that produces excessive exudate, and Whipple also goes on to show where you have used catgut you have a certain amount of necrosis around the suture line, around the catgut, with either plain catgut or chromic.

I think Dr. Maxeiner brought out a very interesting thing in the case cited in regard to presacral neurectomy, which is a wonderful thing. You may remember a number of years ago where, when we had severe cases of dysmenorrhea, we used to do the ordinary Pozzi operation. Occasionally we would get a result, but in most cases we would not. There probably were as many good results with the ordinary dilatation and curettage, as resulted with the Pozzi operation. I believe the case that Dr. Maxeiner illustrated is a wonderful thing, because it brings out the importance of presacral neurectomy in some of these cases of intractable pain in the pelvis. I understand now that with some of these tuberculous bladders, irritable bladders, etc., they are getting wonderful results with presacral neurectomies.

PRESENT STATUS AND MODERN ADVANCES IN THE SURGERY OF THE KIDNEY AND BLADDER

C. D. Creevy, M.D.
Minneapolis

Perhaps I ought to begin by apologizing because about two-thirds of my remarks have to do with the medical rather than with the surgical aspect of urology, since many recent advances have been of a medical nature.

The first development which deserves comment is a diagnostic procedure which has been one of the most useful contributions to medicine in many years, namely excretory or intravenous urography, which was introduced by Swick and Von Lichtenberg in 1929. In its present form it will give adequate and satisfactory information about the form and function of the kidneys in somewhere between 70 and 80 per cent of the cases. If it does nothing more than reduce the necessity for cystoscopic examination by a large percentage it is well worth while from the humanitarian point of view alone. It has reduced the number of cystoscopic examinations and retrograde pyelograms to the extent that in the average case it is necessary to resort to cystoscopy in the study of lesions of the kidney only to settle certain details.

Failures are due either to impairment of renal function or (and this is more often the case in ordinary circumstances) to technical blunders in connection with the timing of the films and with their proper exposure.

Any discussion of therapeutic advances reminds us that this is an age of great enthusiasm for the hormones, and urology has been affected as much as any other specialty. I think that much of this enthusiasm will subside in time, but that remains to be seen. The anterior pituitary and the anterior pituitary-like hormones are now widely used in impotence and in aspermia on the assumption that they stimulate the interstitial cells of the testes to produce testosterone, and the germinal epithelium to produce sperm. There is very definite experimental evidence showing that they do stimulate the elaboration of testosterone, but whether they produce spermatogenesis is open to doubt.

As you know, the anterior pituitary-like hormone has also been widely used to induce descent of the undescended testicle. The preparation was first used clinically by Shapiro in 1930 and has since been rather generally adopted.

Thompson and Heckel among others have made the interesting observation that it is possible, with sufficient dosage over a sufficiently long period of time, to induce hypertrophy of the male external genitalia, including the penis. They have suggested its use in children with hypospadias to increase the size of the penis in order to facilitate operation. Personally I see no objection to waiting until nature produces the enlargement, as she almost invariably will, since the results of operation are as good in the adult as in the child. Apparently there are no ill effects, since the changes produced, with the exception of descent of the testes, disappear shortly after the administration of the drug is discontinued. The exact value of anterior pituitary-like hormone in failure of descent of the testes is pretty hard to estimate because reports of success in the literature range from 25 to 90 per cent. Those reporting lower percentages are inclined to suspect that the very good reports result from the confusion of physiological ectopy with true failure of descent. In the former, spasm of the cremaster muscle holds the testis in the region of the external ring and there is actually no congenital anomaly requiring correction.

Second in present popularity are the testicular hormones. These are divided at the present time into two main groups, the fat-soluble hormones said to come from the interstitial cells and called generally testosterone (andosterone if it is recovered from the urine). It is recommended in hypogonadism in which the testes are very badly damaged or absent. If testes are present and apparently normal or small, anterior pituitary-like hormone is recommended in order to stimulate these testes, whereas if there appears to be no possibility of stimulating the growth and spermatogenesis of the testes, testosterone appears to be preferable. Its successful use in eunuchs has recently been reported both in the medical and in the lay press by Vest and others in Baltimore.

The fat-soluble testicular hormone testosterone is also recommended in prostatic hypertrophy. Its use here is based upon the assumption that in the normal male both estrogenic and androgenic hormones are present, and that with advancing years there is a diminution in the production of male hormone with a relative but not an absolute increase in the estrogens. This idea has originated from the fact that experimentally one can produce a type of prostatic hypertrophy quite unlike that seen clinically, by the administration of estrogens. It is thought to counterbalance this relative excess of estrogen by the administration of the fat-soluble hormone.

We have had a fairly considerable experience with testosterone in prostatism at the University Hospital, and it is my opinion, after treating some thirty or thirty-five cases, that it is probably a form of psychotherapy, but that needs to be verified.

There is a second hypothetical testicular hormone which also has been recommended for prostatic hypertrophy by Lower and his group. It is said to be the water-soluble hormone of the germinal epithelium and is called by him inhibin. Its function is said to be to hold the anterior pituitary in check and to prevent hypersecretion, since it has been shown experimentally that the administration of anterior pituitary or anterior pituitary-like substances to the experimental animal may induce prostatic hypertrophy. He has undertaken to administer this hypotheical hormone by feeding patients dried testicular substance, and has maintained that some 45 per cent of those treated have been very distinctly benefited. By none of these hormones is it possible to reduce the residual urine or to change the size of the prostate, *i.e.*, the improvement is functional.

And now something about urinary antiseptics. I suppose the modern era of urinary antisepsis can be said to have started with the administration of the ketogenic diet for sterilization of infected urine. Its use was based upon the observation at the Mayo Clinic that an unsterile bottle of urine from an epileptic patient who had been kept on a ketogenic diet had been mislaid in one of the examining rooms and had kept fresh and free from odor for four or five days. Since it had not been collected with sterile precautions it was evident that there was something very unusual about this urine. Investigation showed that it contained ketone bodies. This was immediately and successfully employed in infections of the urinary tract by Clark, Helmholtz and others. Fuller subsequently showed that success was due to the presence in the urine of betahydroxy butyric acid, which, for optimum results, should reach a concentration between 0.5 and 1 per cent at a pH of 5.5 or below.

This method of urinary antisepsis is most effective against Gram-negative bacilli. It is an exteremely unpleasant business for the patient. It is difficult to take, and the diet must be controlled absolutely or no ketosis is produced. For that reason, everyone was pleased when Rosenheim, in a search for a stable but effective substitute for betahydroxy butyric acid, found that mandelic acid was not changed in the body, was excreted in the urine, and had about the same antiseptic properties under the same conditions as had the ketogenic diet. It was distinctly less difficult to take. Mandelic acid must also reach a concentration in the urine of between 0.5 and 1 per cent at a pH of 5.5 or below, and it has its best effect in infections with Gram-negative rods and the Streptococcus fecalis.

One or two of you may have heard of the third modern urinary antiseptic which is known as sulphanilimide, and may know something about its history. It was apparently first applied to infections in the urinary tract by Colebrook and Kenney in England, and since has been very widely used in this country. It was apparently first used for gonorrhea by Dees and Colston in Baltimore, and has since been employed by practically every physician in the United States and probably also in Europe. It appears to be effective under favorable conditions in infection of the urinary tract by almost any type of organism except the Streptococcus fecalis. One of the strong points in its favor is that it will sometimes actually sterilize the urine in the presence of Bacillus proteus, something which has hitherto been impossible of accomplishment by any other means. No one, of course, can estimate its exact place in therapy but I don't think anyone can deny that two of the outstanding advances in combating infections in the urinary tract and the genital tract as well, have been the introduction of mandelic acid and of sulphanilimide.

A word about urinary lithiasis. Higgins has applied the previous experimental work of others on rats to the human, and has concluded that, in the human as well as in the rat, urinary stones result from deficiency of vitamin A, which, among other things, produces an alkaline urine and encourages the development of infection. He has undertaken to treat and says that he has been able to dissolve a number of stones in the kidneys by the administration of a high vitamin acid ash diet. Apparently he doesn't believe in taking chances because he doesn't confine himself to the administration of vitamin A but includes B, C, D and a few others for good measure and keeps the pH of the urine below 5.5. He alone, so far as I know, has been able to cause the dissolution of renal stones by this method, which is probably of value chiefly in preventing the recurrence of stones after operation rather than in dissolving stones already formed.

Another thing that may be an advance in connection with lithiasis is an increasing appreciation of the rôle of bacteria, not so much in the production of primary stones as in the production of recurrences following operation. Chief offenders are the urea splitters, of which Bacillus proteus is the worst; staphylococci and other organisms may split urea, produce alkaline urine, and lead to stone formation.

And now a word or two about surgery, since this is a surgical society. One can dismiss the subject of the kidney by saying that recent times have witnessed wider application of conservative operations. The operations themselves, particularly the plastic procedures upon the ureteropelvic junction for hydronephrosis, are not new. Present practice tends to the more frequent removal of stones from the kidney rather than to the removal of the kidney whenever it seems at all likely that the kidney can be saved.

I suppose that division of the isthmus of the horseshoe kidney ought to be mentioned as a recent advance. Although the operation was first done by Rovsing many years ago, it has only recently come into use in this country.

In the surgery of the prostate the outstanding advance has of course been the widespread use and improvement of the operation of transurethral resection, whether by the so-called cold punch or by the diathermy loop. While no one has yet been able to decide just how widely the operation ought to be applied, I think that depends largely upon the ability and the inclination of the individual surgeons. Certainly there is no question but that some 98 per cent of all prostatic obstructions *can* be relieved by transurethral resection. Whether it *should* be applied to 98 per cent is another question. That will depend, of course, upon the late results. As now done by experienced operators, transurethral resection is very nearly as complete an operation as prostatectomy and is applicable to all except the very largest glands and in those cases in which urethral stricture prevents the introduction of the instrument. It is of very distinct value in carcinoma of the prostate which is inoperable so far as cure is concerned, in that it restores to the patient the ability to urinate normally without the assistance of apparatus. It has the advantage over prostatectomy, whether suprapubic or perineal, of a lower mortality, a shorter hospital stay, and of greater comfort for the patient. It has the disadvantage that it is difficult to secure an opportunity to learn how to do the operation because it is a tricky business and is something like golf in that, if you want to do it well, you must do it frequently.

Surgery of the bladder has been marked by a swing to the use of transurethral methods doubtless under the influence of the results of transurethral resection of the prostate. There has been a distinct increase in the application of litholapaxy, which, until recent years, had fallen into almost complete disuse. There has also been an increasing tendency to apply transurethral methods to the treatment of tumors of the bladder. These methods consist in cystoscopic excision with the diathermy loop, fulguration, and the implantation of radon. They have been supplemented by the more effective use of high voltage x-ray therapy based upon the ideas of Coutard (small, frequent, long continued dosage) so that the total amount of irradiation delivered to the objective is much higher than it was with the older methods of larger doses at less frequent intervals.

One other thing that deserves mention is presacral neurectomy for neurogenic vesical dysfunction with retention of urine. While I have undertaken a very painstaking study of its value, I find myself as uncertain after six operations as I was in the beginning. It has also been recommended in interstitial cystitis, a condition in which, as you know, the submucosa is replaced by scar tissue and the bladder is contracted, irritable and painful. Of the two patients upon whom I have done the operation, one is perfectly certain that she has had very definite benefit although she still comes back every three to six months for over-distention of the bladder, a fact which makes me rather skeptical as to its actual value. There has been no increase in the capacity of the bladder but the amount of pain associated with urination has been very definitely diminished. In the other case there was no apparent change. I have used it once in intractable encrusted cystitis with lasting benefit but not cure.

Discussion

Dr. T. H. Sweetser: I wish to call attention to two matters only: first, I wish to mention two aids in the passage of ureteral calculi. The first of these is the taking of 200 grams of glycerine diluted to a liter with water, and imbibed while in a hot tub bath. It was recommended in 1933 by H. Gissel at Rostock. I have tried it a number of times with varying success. The other aid was described by Jarman and Scott of Rochester, N. Y., in 1937—the injection of a 4 per cent solution of avertin crystals into the renal pelvis and ureter above the calculus. Their method is to insert three or four catheters and bougies and leave them 48 hours before injecting avertin before and during removal of the catheters. I have modified the procedure as follows with success: a ureteral catheter was passed to the renal pelvis beyond the calculus and avertin injected as advised by Jarman and Scott; after fifteen minutes a Johnson stone basket with filiform tip was passed, using the catheter as a guide; the catheter was then removed, the basket was removed, bringing the stone with it. I feel that this modification of the procedure is worthy of further trial.

The second matter of special present interest to me is the use of air cystograms in the study of vesical neck obstructions, especially in the study of difficulties following prostatic surgery. I wish to show some illustrative air cystograms now. I feel that this simple procedure, when considered with the rectal palpation and test of residual urine, gives a surprisingly accurate and graphic demonstration of the conditions present.

Dr. E. L. Meland: I have enjoyed very much listening to Dr. Creevy's presentation in newer developments in urology and, inasmuch as he has covered the field so well, there is not much to add. There are two subjects which he did not touch upon which I would like to mention.

The first is radical perineal prostatectomy for early carcinoma of the prostate. This is an operation which was proposed by Dr. Young as long ago as 1904, so the procedure is not new. However, marked interest has been shown in this subject in the last few years. The operation is only applicable to those cases in which there is a small nodule well contained within the capsule without any evidence of extension outside. Obviously, the number of cases to which the operation can be applied is very small. The opportunities for applying this procedure are dependent upon the early recognition of nodules which may be malignant. An attempt should be made to educate the medical profession in general to the possibilities of radical perineal prostatectomy.

The second subject is on the treatment of a certain small number of cases of prostatitis. A few years ago Dr. Thompson described a new method of dealing with dilated ducts in the prostatic urethra which were, virtually, the internal openings of small sub-urethral abscesses. Where this condition exists the proper treatment will, in many instances, lead to a marked improvement in the existing infection in the prostate and, occasionally, practically the eradication of the infection. Those patients in which there are many local symptoms such as burning and frequency are usually relieved of these symptoms by slitting of the dilated ducts and excision of the overhanging edges. It is possible with this operative procedure to evacuate prostatic calculi when they are present.

BOOK REVIEWS

Books listed here become the property of the Ramsey and Hennepin County Medical libraries when reviewed. Members, however, are urged to write reviews of any or every recent book which may be of interest to physicians.

Clinical Laboratory Methods and Diagnosis. Second Edition. R. B. H. Gradwohl, M.D., Director of Gradwohl Laboratories and Gradwohl School of Laboratory Technic; Formerly Director of Laboratories, St. Louis County Hospital, et cetera. 1607 pages. Illus. Price, $12.50, cloth. St. Louis: C. V. Mosby Co., 1938.

Synopsis of Clinical Laboratory Methods. W. E. Bray, B.A., M.D., Professor of Clinical Pathology, University of Virginia; Director of Clinical Laboratories, University of Virginia Hospital, et cetera. 408 pages. Illus. Price, $4.50, flexible binding. St. Louis: C. V. Mosby Co., 1938.

Medicine in Modern Society. David Riesman, M.D., Professor of History of Medicine, and Professor Emeritus of Clinical Medicine, Princeton University. 226 pages. Price, $2.50, cloth. Princeton, N. J.: Princeton University Press, 1938.

Maternity Care In a Rural Community. Maxwell E. Lapham, M.D., Assistant Professor of Obstetrics, School of Medicine, Tulane University of Louisiana, et cetera. 65 pages. Illus. Price, 25c, paper cover. New York: The Commonwealth Fund, 41 E. 57th St., 1938.

Drug Addicts Are Human Beings. Henry Smith Williams, M.D., B.Sc., LL.D. 273 pages. Price, $2.50, cloth. Washington, D. C.: Shaw Publishing Co., 1938.

Scarlet Fever. George F. Dick, M.D., D.Sc., Professor of Medicine, University of Chicago; Attending Physician Billings Memorial Hospital; Editor, Dept. of Infectious Diseases, Year Book of General Medicine; and Gladys Henry Dick, M.D., D.Sc. 149 pages. Illus. Price, $2.00, cloth. Chicago: Year Book Publishers, 1938.

THE VITAMINS AND THEIR CLINICAL APPLICATION. By Prof. Dr. W. Stepp and his confrères. Copyrighted by The Vitamin Products Co., Milwaukee, 1938, printed by The Wisconsin Cuneo Press, Inc. Translation by Dr. H. A. H. Bauman of Minneapolis, Minn.

Dr. Bauman is to be congratulated upon his excellent translation of this original compilation in the German, dated Munich-Wiesbaden early 1936, by Stepp, Kühnau and Schroeder. It is a very opportune time for a review of the subject of vitamins. Presently the American Medical Association has had weekly articles since early February, 1938. These articles are highly repetitive, and one gleans from the accompanying bibliography the enormous amount of research or printed matter that is appearing in terms of nutrition and protective elements. The fact that Bauman's translation

You Haven't Seen Us Here Before!

This is John Wyeth & Brother's first ad in your State Journal, and we're glad to be here to wish you a Happy and Prosperous New Year—Also to tell you about

SILVER PICRATE *Wyeth*

An effective *Council Accepted* Treatment for TRICHOMONAS VAGINALIS VAGINITIS

AN effective treatment by Dry Powder Insufflation to be supplemented by a home treatment (Suppositories) to provide continuous action between office visits. Two Insufflations, a week apart, with 12 suppositories satisfactorily clear up the large majority of cases.

SILVER PICRATE—a crystalline compound of silver in definite chemical combination with Picric Acid. Dosage Forms: Compound Silver Picrate Powder—Silver Picrate Vaginal Suppositories. *Send for literature today.*

JOHN WYETH & BROTHER, INC. • PHILADELPHIA, PA. • WALKERVILLE, ONTARIO • LONDON, ENGLAND

has been brought to the attention of the profession through one of the manufacturers of vitamins may possibly cause many physicians to neglect and pass up this work as just another sales promoting leaflet. The work put into this translation by Dr. Bauman deserves a much better reception, and I recommend it to all those who are interested in finding out, in addition to what may be gleaned from our own American literature, the contentions, beliefs and offerings of Continental Europe as well.

We may as well be frank in dealing with the subject of vitamins at ths time: there has been such an offensive propaganda of general and radio advertising that the real accomplishments in the field of vitamins may pass with very inadequate review, and prejudices may keep us from sifting out the features that are extremely helpful and meritorious. Those who will take the time to read this book in Bauman's lucid reproduction will be greatly rewarded. The chapters are well chosen and there is no tendency to drift so far towards the chemical or biological research viewpoint that one is lost in a maze of technical debris. On the contrary, each chapter is very carefully drafted, with a desire to arrive at judicious clinical application, and the supporting bibliography attests the large amount of effort expended in the compilation.

Fortunately, extra attention is given to B and B Complex, and the material conforms very well with the conclusions that are being gradually drawn from our own American experience. Much less attention is given, for example, to Vitamin E, and the short chapter thereon attests its biological significance as far as man is concerned. Research in the department of vitamins is advancing so rapidly that it is not unexpected that there is little in reference to vitamin K and the bleeding of jaundice.

The appendix added by Dr. Bauman for the English addition comprises fifty pages, with a summary of the functions, possible results of deficiencies, and the results of a total lack of the various vitamins listed. There then follows the bibliography for each vitamin. The printing is exceptionally well done. I highly recommend the book.

E. L. Tuohy, M.D.

TREATMENT BY DIET. Third Edition. Clifford J. Barborka, M.D. 642 pp. Illus. Philadelphia: J. B. Lippincott Co., 1937. $5.00.

No change has been made in the general plan of this edition but the author has added a discussion of the present status of the vitamins and the use of protamine zinc insulin, and the subject of obesity is somewhat amplified.

The volume is divided into five main sections: Diet in Health, Application of Diet Therapy, Diet in Disease, Routine Hospital Diet, and Appendix.

Diets for diseases in which diet is of paramount importance and for conditions in which it is of varying importance are discussed and the objects of the diet in each case are given. Food tables specify the special kind of food which is lacking in a given case, calorie requirements and amounts in gram weight and household measure.

Various types of diets such as non-residue, liquid, soft, light or bland are given and also food which is appropriate for tube feeding.

The Appendix consists of a table of the average composition of the commonly used foods.

The author believes that lack of qualification or interest in the subject of obesity sends many of these individuals to quacks or leads to self-dieting. He also finds more interest in the medical profession in the use of foods as an adjunct to treatment.

The author has presented the subject clearly and concisely and his book deserves a place in the physician's library. Such a book is opportune. Malnutrition is prevalent. There has been voluntary dieting to procure a slender figure and during the depression involuntary dieting; and now there is danger of replacing supporting foods by vitamin (?) capsules.

Nellie N. Barsness, M.D.

ANUS, RECTUM, SIGMOID COLON: diagnosis and treatment. H. E. Bacon, M.D., Philadelphia: J. B. Lippincott Co., 1938.

This is undoubtedly the most complete book on this subject to date.

There are over 800 pages describing, in complete detail, all the diseases and deformities of the anus, rectum and sigmoid, as known today, with numerous illustrations and actual photographs.

Dr. Bacon is very liberal in discussing the opinions of other physicians and surgeons but he is not very generous in expressing his own beliefs and experiences. The bibliography and index have been most painstakingly prepared. References are made to practically all the literature, on this subject, written in this country and abroad. It is, therefore, extremely valuable as a reference book.

Dr. Bacon's book is so complete and detailed that it can be profitably read by either general practitioner, surgeon or proctologist.—H. W. Christianson, M.D.

OUTLINE OF ROENTGEN DIAGNOSIS. Leo G. Rigler, M.D., Minneapolis, Minnesota. 212 pages. 254 illus. Student's edition, $3.00. Complete edition (with charts), $6.50. Philadelphia: J. B. Lippincott Company, 1938.

Roentgenology covers such a wide field in diagnosis that it is difficult to enclose in one volume a textbook sufficiently detailed to be of great value. Dr. Rigler has met this problem by presenting his material in outline form. The result is so successful that this volume is not only a valuable text for medical students and physicians, but is also a ready reference book for radiologists.

The text is adequately illustrated by excellent reproductions of roentgenograms and by a new method of diagrammatic drawing of the findings observed in radiographs.

This book can be highly recommended.

ADVANCES IN THE PREVENTION AND TREATMENT OF CONTAGIOUS DISEASES OF CHILDHOOD*

ERLING S. PLATOU, M.D., and PAUL F. DWAN, M.D.

Minneapolis, Minnesota

CONTRIBUTIONS to the field of contagious disease prevention and treatment have become more numerous than ever during the past decade. Although a detailed knowledge of these is desirable, the scope of this article is limited to presenting a condensed survey of accumulated data focused on certain practical conclusions regarding a subject which is of such vital importance.

Statistical analysis of mortality rates in the State of Minnesota shows a general decline in the deaths from the more common diseases of childhood since 1915. A study in the allocation of mortality by age groups, however, reveals the fact that the deaths from diphtheria, scarlet fever, measles and pertussis in the pre-school age have remained practically unchanged during this period. A great deal of publicity has been given to immunization, hygiene, early diagnosis and treatment of contagious diseases in the schools of Minnesota, but apparently too little has been said relative to the need of instituting specific protection very early in life.

Diphtheria

As a result of immunization, Schick testing and detection of carriers by culture, the percentage of deaths in the school ages has declined materially since 1915 (Fig. 1). Little or no change in the mortality rate is evident for the infant and the pre-school child during this period of time, however. More attention must, therefore, be given to routine immunization against diphtheria during infancy and the optimum time for this procedure is at the age of six months. Toxoid is superior to toxin-antitoxin for this purpose and can be given in doses of 0.5 c.c. followed in three weeks by one c.c. About 90 per cent of cases so inoculated will show a negative Schick reaction after six months. Even better results (99 per cent negative) have been accomplished by giving a third dose (1 c.c.) one month later.[24]

Alum precipitate toxoid has been heralded[6, 7, 8, 22, 28] as being superior to all methods of diphtheria immunization since, due to its insolubility, it is more slowly absorbed and has a resultant prolonged antigenic action. It is prepared by complete precipitation with alum, which results in no loss of specific antigen, and simultaneously removes much of the undesirable protein. It is claimed that injection of five to ten units (0.5 c.c.) into children two to six years of age has resulted in 96 per cent negative Schick tests. The advantages of this preparation are stability, absence of sensitization to animal serum and the potency of the antigen. With improved methods of refining, the slight hazard of occasional abscess formation may be eliminated. Regardless of what antigen is used, however, it must be emphasized that multiple doses have been shown to produce a more sustained high level of immunity.

Schick tests should always be performed at intervals after immunization. Infection[15] and other factors may cause a diminution or even a loss of immunity.

Of greatest importance in diphtheria prevention is the early administration of toxoid. Godfrey[5] has demonstrated that immunization of 50 to 70 per cent of school children has reduced the diphtheria morbidity in a community very little while the addition of 30 per cent of pre-school children to the program has resulted in practically eliminating the disease.

*Presented before refresher course in Pediatrics—Center for Continuation Study—University of Minnesota, October 1, 1938.

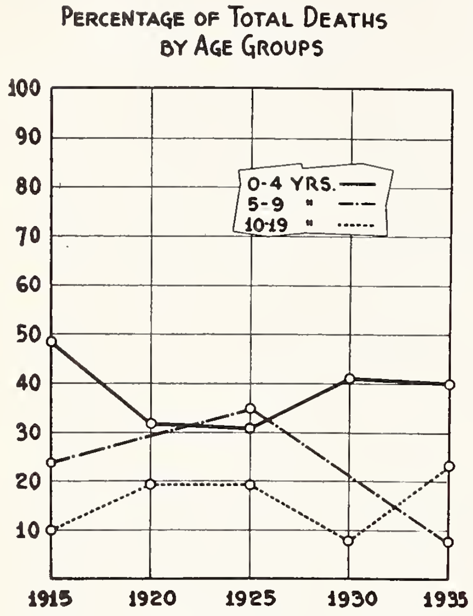

Fig. 1.

Park has said, "It is the infant who needs immunization most and is bothered by it least."

Scarlet Fever

Inspection of Figure 2 reveals the fact that one-third of the total deaths from scarlet fever in Minnesota occur in the pre-school age group and that there has been but little relative reduction in the mortality for this class during the past eighteen years. Furthermore, the deaths in the early school period (five to nine years) constitute an additional 30 per cent of the total mortality, so that about two-thirds of the total deaths are sill occurring previous to the tenth year of life.

Doubtless much of this early mortality could be avoided by the detection of early and mild stages of the disease, as well as of the transitory carrier state of immune contacts. More widespread utilization of the blood agar culture plate for hemolysis, the Dick test, the blanching test, careful isolation and serum should be emphasized.

Prevention by Immunization.—During recent years the concept of a causal relationship between a certain strain of hemolytic streptococcus and scarlet fever has been gaining favor. Although considerable unanimity of opinion exists today with respect to the specific etiology of this disease, nevertheless attempts to prevent it by inoculations with a toxin derived from the scarlet fever strain of streptococcus is not being practised widely. The failure to do this may be justified on the basis of the poor results obtained in the past following the administration of presumably inadequate doses of scarlet fever toxin. When the methods recommended by the Scarlet Fever Committee were used, the objections by patients to five inoculations and the occurrence of occasional reactions, together with doubt in the minds of many physicians, became factors which contributed to the reluctance of many to advocate immunization to their patients.

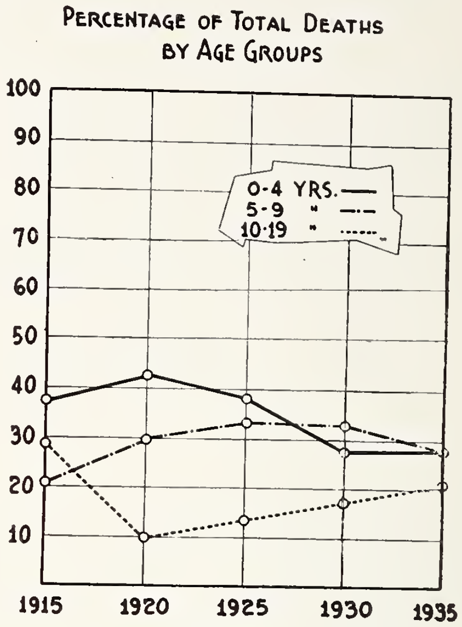

Fig. 2.

A question which may be properly raised and must be answered before specific prevention can be urged, is whether the method of immunization recommended by the Scarlet Fever Committee really has merit sufficient to justify its adoption.

The medical literature of the past ten years furnishes us with more or less data on over 50,000 inoculated individuals. Although a great many of the reported studies are lacking in detail and in proper controls, a sufficient number are suitable for analysis, so that we may arrive at fairly safe deductions relative to the protective value of inoculations with the Dick toxin.

In the present study, a change in reaction of the Dick test has been discarded in favor of subsequent case incidence as a criterion of immunity.

Table I presents a most exacting trial of the toxin's efficacy. Here are collected the reports on persons known to be susceptible by previous test. All of these persons had a relatively high degree of exposure to infection and were observed over considerable periods of time. A compilation of these data reveals the fact that among 20,000 susceptibles inoculated in accordance with the recommendations of the Scarlet Fever Committee, only one subsequent case was reported over a period of about three years. The annual incidence of the disease was 1.65 per 100,000.

TABLE I. SUSCEPTIBLE CASES REPORTED IN LITERATURE
Patients were immunized according to the recommendations of the Scarlet Fever Committee and annual incidence of scarlet fever per 100,000 among those immunized.

Author	Susceptibles (Dick positive)	Exposure	Time Observed	Subsequent cases
Dick	11,584	Internes & Nurses	5 years	0
Rhoads	298	Nurses	3½ years	0

Total	20,000			

Annual case incidence per 100,000........................1.65

*Preparation and dosage not entirely up to standard of Scarlet Fever Committee.

TABLE II. UNIMMUNIZED CONTROL CASES REPORTED
The annual case incidence of scarlet fever per 100,000 population among the unimmunized.

Author	Susceptibles and Immunes (No Dick test)	Exposure	Time Observed	Subsequent Cases	Cases per year
Dick		Internes and Nurses	5 years	(37)	(7.4)
Rhoads	182	Internes and Nurses	3½ years	15	4.3
Rhoads	206	Epidemic	10 months	15	13.5
Kiefer		Institution	3 years	(10)	(3.3)
Dudley	23	Institution Epidemic	2 months	2	12.0
Hektoen	516	Contagious disease nurses	10 years	40	4.0
Platou	861	Contagious disease attendants	6 years	55	9.2
Boynton	150	Nurses	4 years	8	2.0
Total	1,938				

Annual case incidence per 100,000......................2,317

Some of the studies included in the above table did not specifically state the number of controls. For this reason the uninoculated group reported in Table II is much smaller, although the cases included are comparable, since they are from the same institutions. It is noteworthy that these were not Dick tested and, therefore, represent a less susceptible group than the one in Table I. Over two hundred cases of scarlet fever occurred among these individuals during a period of several years observation. The annual incidence per 100,000 computed from 2,282 of these which can be utilized statistically is, therefore, 2,317.

The most convincing evidence regarding the merit of adequate immunization is found in a study of nurses from the Central School of Nursing at the University of Minnesota. During the past five years, two hundred and sixty-four susceptible nurses have been inoculated according to the recommendation of the Scarlet Fever Committee. Only one of these* has had scarlet fever during this period whereas twelve out of two hundred and fifty non-tested affiliate nurses have contracted the disease in the same period of time. Since both groups did similar work in their apprenticeship on the scarlet fever wards, they are particularly comparable.

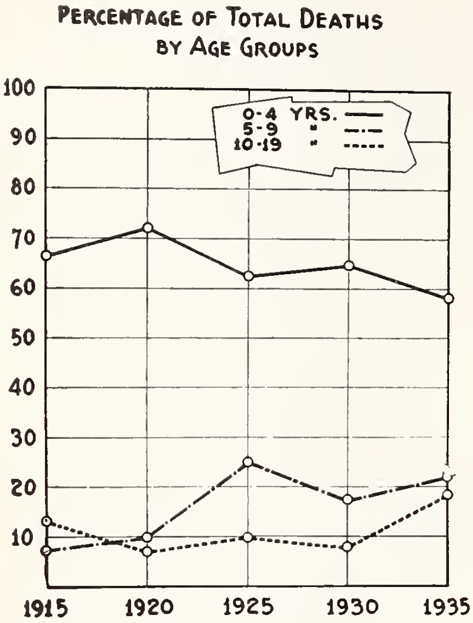

Fig. 3.

It would seem from the evidence available to date, that graduated doses of pure scarlet fever toxin administered to the point of a negative Dick test, has definite merit, and the procedure is warranted in spite of certain objections which operate to prevent its widespread use. The practice of immunization against scarlet fever for the prevention of institutional and community epidemics seems particularly desirable.[16]

Treatment.—Septic cases of scarlet fever with exudative manifestations in the nose and throat are most effectively treated by intravenous administration of large doses of convalescent human serum or by repeated immuno-transfusions. Toxic cases that can be treated early in their course are greatly benefited by large doses (12 to 18,000 units) of scarlet fever antitoxin. Sulfanilamide or neoprontosil in continued doses of .03 gm. per pound per twenty-four hours have recently been shown to effectively complement the specific serum and markedly reduce complications.[20] It is believed that this drug acts synergistically with the actively produced or passively conferred specific defenses of the body.

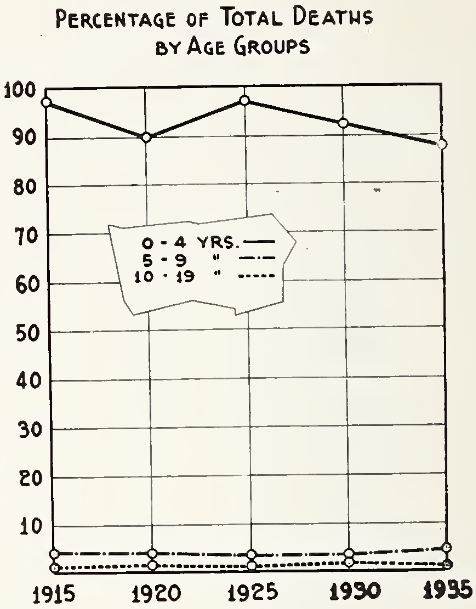

Fig. 4.

Measles

Attempts at active immunization against measles by Herman, Degkewitz and other workers have failed. Convalescent serum, first used by Weisbecker[27] in 1896, revived by Cenci,[2] Zingher[29] and many others, has probably been neglected too much. Elterich[4] pointed out that measles is a serious disease in the young, causing 8,000 to 10,000 deaths annually in the United States, most of which occur below the age of three years. Kaiser[9] contends that measles is responsible for 6 per cent of all child deaths, and states that the mortality is 55 per cent under two years of age. Lord[11] stresses the advantage of using whole citrated blood from adults in the family and believes in giving it after the appearance of the rash, to insure permanent immunity. Dulitskiy[3] and de Sousa[23] used adult blood and placental blood in doses of 20 c.c., and report attenuating the disease and reducing the mortality in similar groups of infants from 39.6 per cent to 4.6 per cent. They believe the serum loses its potency in thirty days. McKhann[12] prepared extracts of human placentas by precipitation with ammonium sulphate. Suspensions of this extract in saline, when injected into children exposed to measles, had a protective effect similar to that of convalescent serum.

---

*The nurse who contracted scarlet fever was immunized to the point of a negative Dick test eighteen months prior to infection. A Dick test performed six months before her attack of mild scarlet fever was positive, but she was not reimmunized.

Immediate prophylaxis is best accomplished by giving 20 c.c. of convalescent human serum subcutaneously, combined with sulphanilamid by mouth.

In our experience,[18] convalescent serum, 6 to 10 c.c., or blood, 12 to 20 c.c., given intramuscularly between the fifth and ninth day of incubation have resulted in the greatest degree of attenuation and the least reaction. The production of prolonged immunity is not interfered with by this method.

Though most of us are prone to entertain the thought that measles is "just measles," inspection of mortality Figure 3 should convince us that such a concept is wrong; that not only should convalescent serum or blood be used as a preventive in debilitated children but as an attenuating agent in every small child exposed to measles. In pre-eruptive measles, large doses of convalescent serum (or immune blood) have recently been shown to modify the disease in a rather striking manner. The effects of sulfanilamide on streptococcal complications is now being studied.

Pertussis

Of the diseases under discussion, pertussis takes the highest toll in infancy and yet our methods for its control are the least effective (Fig. 4). Early diagnosis by means of blood studies (leukocytosis and relative lymphocytosis) the cough plate culture (with chocolate agar) and the isolation of the infected school child, may help to protect infants from exposure and defer the onset of the disease to a later period in life. However, in the average home, contacts are so intimate that these measures are inadequate. The eventual solution of the problem must be through immunization. Much progress has recently been reported in this field. Madsen[13] of Denmark probably revived the hope of an effective vaccine for prevention with his studies in Iceland. Sauer[21] reported a study of 396 children who were observed for five years following injection of 80 to 100 billion organisms in a vaccine prepared from fresh hemolytic strains of B. pertussis grown for forty-eight hours on Bordet-Gengou media to which human blood had been added. He contends that immunity results after a four-month period.

Kruger and Frawley[10] have reported studies with a vaccine prepared by destroying bacilli without resorting to heat and using very large dosage. Bailey[1] has produced a serum of high titre from birds which seem relatively immune to the B. pertussis. The studies of Rich[19] throwing some doubt on the Bordet-Gengou bacillus as the specific etiologic agent in pertussis may be somewhat disturbing to enthusiasts who favor vaccines made from this organism. From available data, however, it seems that freshly prepared Phase I type of vaccine offers some promise of sustained partial immunity especially if repeated (annual) antigenic stimuli are utilized.

A marked attenuating effect from large doses of convalescent serum given after exposure or early in the disease has been observed in a group of children studied by Bradford.

Erysipelas

Erysipelas is an extremely serious disease in infancy. The newer treatments are antitoxin, human convalescent serum, roentgen irradiation, ultraviolet irradiation and sulfanilamide.

Symmers and Lewis[25] have reported at length on the use of antitoxin. It is prepared by immunizing horses with eight strains of streptococcus, and is preferably given by intramuscular injection. They believe it helps to control the immediate attack and reduces mortality.

Concentrated roentgen ray therapy in erysipelas was first introduced in 1926.[17] The distance used was 10 inches, with 2 mm. aluminum filter, 111 kilovolts, 5 milliamperes, 5 minutes. It was found to be effective in limiting the spread of the disease and comparative studies indicate that it reduces mortality.

Although roentgen irradiation is effective, it has drawbacks such as inherent dangers, expense, lack of proper facilities, and that it must be given by a trained radiologist. Short wave ultraviolet therapy[26] causes a somewhat similar reaction in the skin. It is inexpensive, applicable, usually requires only one treatment although it may be repeated, and is without danger. It must be given at a distance of eight inches with an exposure of eight to fifteen minutes, one inch of the contiguous normal skin being included in the treatment area. The combined use of roentgen or ultraviolet irradiation convalescent serum and sulfanilamide definitely reduces the mortality of erysipelas. Transfusion is a helpful adjunct.

Epidemic Meningitis

When this disease is considered in the light of its pathogenesis, the rationale of certain therapeutic innovations may be more acceptable.

Meningococci invade the blood stream from minute foci in the upper respiratory tract. Subsequent loss of integrity to peripheral vessel walls occurs due to action of the toxin. This results in perivascular inflammation and hemorrhage, and organisms along with erythrocytes and leukocytes thus gain access to the skin or arachnoid or both. Meningitis per se is usually a late development.

Massive doses of highly antitoxic serum given intravenously to quickly neutralize the toxin have reduced the case fatality rate in the Chicago area from about 50 per cent to 15 per cent. Sulfanilamide alone has effected a high percentage of cures. The latter is now believed to be highly synergistic to serum (or other natural defenses in the body). Oral therapy with the drug is adequate due to its rapid absorption into all tissue fluids and the combined treatment is so satisfactory that intrathecal administration of either agent is now rarely resorted to. Fever therapy has proved effective in chronic meningitis.

Smallpox

In recent years, aside from the well-known glycerinated-vaccinia-vaccine, several newer antigens have been recommended: the chorio-allantoic chick embryo vaccine prepared according to the method of Goodpasture and the lyophile tissue vaccine of Rivers. The latter is administered intracutaneously and is particularly useful when children with skin diseases require vaccination, and when the vaccine has to be shipped under climatic conditions which may readily destroy the potency of the vaccine.

Rabies*

During the past fifty years, the original Pasteurian procedure has been modified primarily to increase the immunity and secondarily to reduce the complications in form of paralysis or even infection (Högye's method). The fixed virus is subjected either to heat or to the action of chemicals such as carbolic acid or ether. The so-called Semple or phenol treated vaccine is now quite generally used, and although the statistics regularly presented by McKendrick (Bull. Health Organization, 6:17, 1937) would indicate that the killed vaccines give rise to a substantial degree of immunity when given in adequate dosage, there is definite evidence that some preparations on the market are inactive and that, as a whole, they are inferior to vaccines in which the virus is alive but attenuated. On a comparative basis, the etherized vaccines prepared according to Alivisato's method are generally considered superior to the Semple vaccine.[29] Since the immunity mechanism in rabies is by no means understood, it is indeed difficult to evaluate the protection which may be conferred by certain preparations. It is not unlikely that the resistance of the ganglion cells to the virus is independent of the antibodies found in the circulation. For example, a veterinarian, who had been bitten on the thumb by a rabid dog, was thoroughly treated with Semple vaccine, developed neutralizing antibodies in his serum and yet succumbed to rabies.

While there are several objections to the use of live vaccines in the prophylaxis of most diseases, the fact that the case mortality rate in rabies is so high and the patient is already infected at the time of vaccination one seems warranted in taking greater risks when there is known infection. The so-called mixed treatment consisting of etherized vaccine followed by Högye's dilution method or vice versa seems to be justifiable in deep bites with localization on the head. Those who are frequently brought in contact with the problem of anti-rabic treatment may profitably consult a recent monograph by Mario J. Van Stockum (New Principles of Antirabic Treatment, Hague, 1935).

Tetanus*

Tetanus antitoxin acts not by interfering with the germination of the spores but by neutralizing the toxin as fast as it is formed. It should be used prophylactically in cases in which there is danger of contamination of a wound with manure, soil, stable dust, et cetera. The initial dose of 1,500 units (800 to 1,000 units) should be repeated on the fifth day after the initial dose. In fact, third and even fourth injections may be indicated when the wound is very bad. Since the protection wears off in the course of two or three weeks, sensitization with horse serum is undesirable and sometimes severe serum reactions accompany the treatment, there is a tendency to reinforce the passive immunity by means of active immunization. The latter procedure is equally advisable in children, who are constantly subject to injuries which may be followed by tetanus. The French Army has pioneered in this field of active immunization. Postinfectional preventive serum therapy is now enhanced by the injection of 1 c.c. of tetanus toxoid about fifteen minutes after the administration of the serum followed by two injections of 2 c.c. of toxoid at two weekly intervals. Such a treatment raises the antitoxin level of the patient's serum over one quarter unit per cubic centimeter, and although at least 1/200th unit may be demonstrable nine years after the injection of the toxoid, it is advisable to repeat the treatment every time a new injury is acquired. One injection of toxoid seems to push the titer over the minimal requirements. Ramon recommends highly the systematic active immunization of children against tetanus by using the combined diphtheria-tetanus toxoid mixture. Three injections at three week intervals in dosages of 2 c.c. are used in France. The usual contraindications, malnutrition and skin diseases equally apply to this procedure. As a rule, the local and general reactions are observed in about 20 per cent of the vaccinated regardless of the dose. Tetanus-toxoid alum precipitated has been used by McBryde and by Holdman in this country. Two injections of 1 c.c. each at an interval of two months followed by a third injection at the time of injury permit the practitioner to immunize the allergic child effectively and securely against tetanus.

---

*Quoted verbatum from K. F. Meyer.

Whether or not antitoxin is of any value in man when given subsequent to the development of tetanus is a question that has received no definite answer. The evidence merely goes to show that in therapeutic treatment of tetanus, large and repeated doses of serum reduce the mortality. In practice, it seems advisable to administer the serum by the intravenous and intramuscular route. Patterson, who treated twenty-six consecutive children suffering from tetanus with only seven deaths (26 per cent mortality), used the intravenous and intramuscular route and enormous doses of serum (120,000 to 1,970,000 units). His critics claim that he could have reduced the mortality even further had he adopted the intrathecal administration of one dose of serum (20-30 c.c.) by the cisterna magna route as practiced by Yodh in India. The lumbar puncture route is quite generally considered less effective and even harmful.

ESSENTIALS IN THE DIAGNOSIS OF CONGENITAL HEART DISEASE*

THOMAS J. DRY, M.B.

Rochester, Minnesota

AN UNDERSTANDING of the ontogenesis of the different congenital defects provides not only a list of the morphologic variations which congenital cardiac anomalies may assume, but also permits a clear understanding of the manner in which each anomaly modifies or burdens the physiologic mechanism of the cardiovascular apparatus. These constitute fundamental requisites for the clinical recognition of congenital heart disease in its various forms.

The Genesis of Cardiovascular Anomalies

If one begins with the premise that the cardiovascular system recapitulates its ancestral history during the course of its own development, it is reasonable to expect that, if arrest of development does occur, it will represent the adult form of one of the lower vertebrate series, dependent on the stage at which arrest takes place. The intermediate stages are, in fact, particularly well illustrated in the developing mammalian heart because it assumes functional activity at a very early stage of gestation. As in its phylogenetic history, it starts as a simple tube-like structure with the same subdivisions as the adult fish heart (Fig. 1*a*). Expressed in the simplest form its development from then on consists essentially in: (1) septal formations dividing the auricle, the ventricle, the bulbus cordis, and the common aorta or truncus arteriosus each into two sections (Fig. 1*b*); (2) torsion of the cardiac tube; (3) development of the bulbus cordis; (4) the incorporation of the sinus venosus into the right auricle (Fig. 1*b*); (5) the evolution of the aortic arches, some being obliterated, others becoming the permanent aortic arch, pulmonary artery and their branches; and (6) closure of fetal channels after birth.

Septal formations.—This process is the physiologic response on the part of the cardiac tube to the evolution of a lung-respiratory system so that the venous and arterial systems eventually become completely separated from one another. Any of these septal formations may be incomplete, resulting in any one of a variety of well-known defects (Table I). The cor biloculare in which no septa have developed is the replica of the fish heart. The amphibian form is represented by the cor triloculare biatriatum in which the interventricular septum is absent. Small interventricular septal defects, such as the maladie de Roger, resemble the adult form of the heart of some of the higher reptiles.

Now if it is realized that the different developmental processes which are being described are occurring more or less synchronously, it is apparent that multiple sites are liable to be involved, though isolated anomalies, of course, frequently occur. Normally, septal formations are complete after the seventh week of fetal life.

Torsion of the cardiac tube.—At an early stage the cardiac tube becomes kinked on itself by virtue of the fact that its extremities are relatively fixed as the primitive heart elongates (Fig. 1*b*). The torsion to which I refer, however, applies to a clockwise rotation of the bulboventricular end of the cardiac tube during which the aorta moves toward the left and partially behind the commencement of the pulmonary artery. If one will examine the anterior aspect of the adult normal heart this relationship will become clear. This torsion is necessary in order to bring the left ventricle into juxtaposition with that part of the truncus arteriosus which is destined to become the aorta, and the right ventricle into juxtaposition with the pulmonary artery. As in the adult heart of certain reptiles, there is a transitory stage in the human heart in which there are two aortæ connected with the left ventricle, each with two cusps. In the process of torsion, the right aorta is obliterated whereas the left remains open to become the outflow chamber of the left ventricle. If this process of torsion is arrested, the aorta is left in a dextroposed position, in which case the right aorta persists instead of the left, or the right and left aortæ may fuse to form a large aortic trunk. In either case this dextroposed aorta, instead of bearing the normal relationship to the left ventricle, overrides the interventricular septum (which is usually incomplete) and the right ventricle (Fig. 2). In other words the great vessels (the aorta and pulmonary artery) are transposed, and this transposition may be present in varying degrees depending on the degree of torsion that has occurred. Sometimes there is a small niche in the right ventricle which represents the obliterated right aorta. It is extremely likely that other developmental defects will accompany such a gross deviation from the normal, such as imperfect septal formations and incomplete evolution of the bulbous cordis.

---

*From the Section on Cardiology, The Mayo Clinic, Rochester, Minnesota. Read before the meeting of the Minnesota State Medical Association, Duluth, Minnesota, June 29 to July 1, 1938.

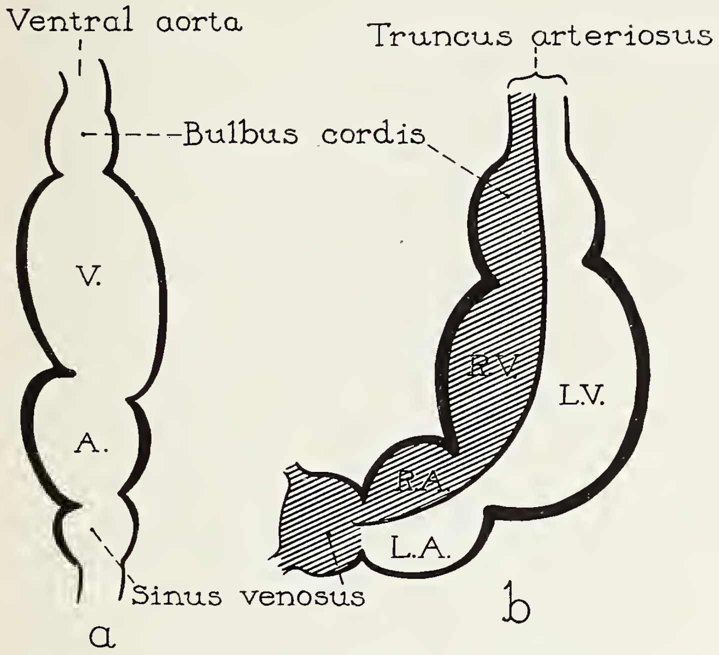

Fig. 1*a*. Fish type of heart, which is similar to the heart in the fourth-week human embryo; *b*, septal formation. The sinus venosus is incorporated in the right auricle, the bulbus cordis becomes part of the right ventricle (mainly) and of the left ventricle, and a clockwise rotation occurs in the bulboventricular part of the cardiac tube.

Here, then, one sees the genesis of one of the important and interesting anomalies representing arrest at the reptilian stage, namely, the tetralogy of Fallot. This consists of dextroposition of the aorta, with an interventricular septal defect, pulmonary stenosis and an hypertrophied right ventricle. Cusp anomalies are frequently associated with the tetralogy, especially in the form of bicuspid leaflets which are, interestingly enough, the normal for the reptilian species.

The development of the bulbus cordis.—Essentially this consists of the incorporation of the major portion of the bulbus into the right ventricle, to form the conus arteriosus, and a smaller portion into the left ventricle. If this process is incomplete, the corresponding ventricle will be constricted or stenosed in that region. Thus in the case of the left ventricle there will be a stenotic band below the aortic valve, that is, a subaortic stenosis. Its counterpart in the right ventricle consists of a subpulmonic or infundibular stenosis.

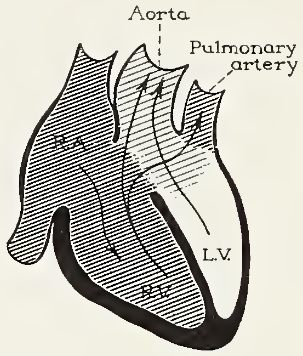

Fig. 2. The tetralogy of Fallot, showing a large aorta which is dextroposed and overrides the interventricular septum. The latter is incomplete. The pulmonary artery is stenosed and the right ventricle is hypertrophied. The left auricle is not indicated in this diagram.

In the genesis of some of the stenotic congenital lesions, fetal inflammatory processes probably play a part.

The incorporation of the sinus venosus into the right auricle.—In the adult heart the sinus venosus is represented by that part of the right auricle which receives the blood from the superior and inferior venæ cavæ anatomically known as the sinus venarum.

The development of the aortic arches.—Briefly stated, there are six pairs of aortic arches connecting the primitive ascending aorta to the primitive descending aorta. They are not all present at the same time. The left fourth arch becomes the aortic arch. The right fourth arch forms the innominate artery and the beginning of the right subclavian artery. The sixth arch gives origin to the pulmonary artery, and on the left side, to the ductus botalli.

The chief anomalous developments met are persistence of both fourth arches and persistence of the right arch in place of the left. The latter arrangement is closely related to coarctation of the aorta. The very plausible explanation has been given that if for any reason the left fourth arch becomes stenosed, then one of two terminations results, namely, coarctation, or the right fourth arch may remain patent, forming the aortic arch.[3] In the latter instance the patency of the right arch is salutary; it usually runs over the right bronchus and behind the trachea and esophagus to join the descending aorta. The left arch is here represented by the left subclavian artery, the stenosed fourth arch and a diverticulum which would have formed that part of the aortic arch between the point where the ductus botalli joins it and the descending aorta if the left arch had been normally patent (Fig. 3). Coarctation of the aorta is frequently associated with aneurysms of the circle of Willis.[4,15] Permanent patency of the ductus arteriosus (botalli) should be considered together with anomalies of the aortic arches, as the former is derived embryologically from the latter. The opening up of the pulmonary circulation after birth usually leads to gradual closure of the ductus. Should conditions remain such that pressure in the pulmonic circuit and the aortic arch remains the same as before birth, the duct will remain patent. Patency of the ductus is frequently associated with other anomalies of the aortic arches.

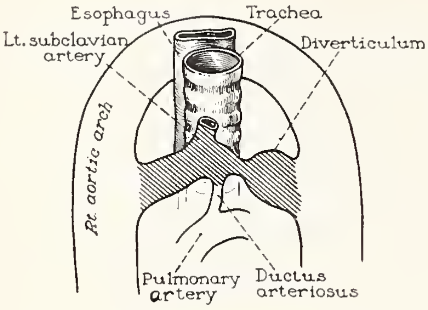

Fig. 3. Persistent right aortic arch, representing the right fourth aortic arch. Note its relation to the trachea and esophagus. The shaded part represents the left fourth arch which normally becomes the aortic arch.

Closure of fetal channels.—This refers to the closure of the ductus arteriosus and the foramen ovale.

Classification.—Associated with each of these processes, anomalous developments may occur and congenital cardiac lesions conveniently classify themselves under the corresponding subdivisions shown in Table I.

Such a classification is self explantory and easily remembered. Viewed in this light, the corresponding physiologic disturbance caused by each anomalous condition is readily understood and the symptoms and physical findings are more readily explained. By the same token it becomes apparent when cyanosis will supervene and when it will not. There is, therefore, no particular advantage in dividing them further into clinical groups.

TABLE I. CLASSIFICATION OF CONGENITAL HEART DISEASE

I. Anomalies associated with septal formation:
    1. Cor biloculare
    2. Cor triloculare biatriatum
    3. Cor triloculare biventriculare
    4. Auricular septal defects
    5. Ventricular septal defects
    6. Persistent truncus arteriosus
II. Anomalies associated with torsion of the cardiac tube and
III. Anomalies associated with development of the bulbus cordis:
    1. Subaortic stenosis
    2. Pulmonary stenosis
    3. Transposition of great vessels
    4. Tetralogy of Fallot
    5. Eisenmenger's complex
    6. Anomalies of the aortic and pulmonic valve cusps
IV. Anomalies associated with development of the aortic arches:
    1. Persistent right aortic arch with isthmus stenosis of the left arch
    2. Double aortic arches
    3. Coarctation of the aorta
    4. Anomalous origin of vessels arising from the aortic arch
    5. Patent ductus botalli
V. Dextrocardia
VI. Anomalies of the coronary vessels

Certain Facts and Findings Which Should Lead One to Suspect the Presence of a Congenital Cardiac Anomaly

Bruits not explainable on the basis of the conventional acquired valvular lesions.—Certain murmurs are described as being diagnostic of particular congenital anomalies. Thus, the so-called Roger murmur of a patent interventricular septal defect was originally described as a murmur which begins with systole and is prolonged to such an extent "that it entirely covers the natural tic-tac of the normal heart sounds"; the continuous or "machinery" murmur in the second left interspace is very characteristic of patency of the ductus arteriosus. What has not been sufficiently stressed is that the distribution of the murmur may be as important as the character of the murmur. Thus, in certain cases, a patent ductus botalli is associated with a soft systolic murmur heard to the left of the sternum, but one's suspicions should be aroused when such a murmur in this area is equally well heard near the left shoulder. No warning too strong can be voiced against making any diagnosis on the presence of systolic basal murmurs alone, since these murmurs occur in the absence of any organic cardiovascular disturbance, particularly under conditions, such as mere excitement or hyperthyroidism, which speed up the circulation. In many cases systolic basal bruits have been shown to be the result of minor degrees of calcareous aortic disease.[7] In any case of organic heart disease in which a systolic murmur is present the murmur will invariably be associated with other physiologic disturbances of the cardiac mechanism, which in themselves will supply the collateral evidence which must be present before a positive diagnosis is justifiable. This applies to any type of organic heart disease.

Thrills.—These are frequently present over the areas of maximal intensity of the bruits, and both thrills and bruits become more readily elicited clinically after exercise.

Evidence of venous-arterial shunt, with the usual manifestations: cyanosis, polycythemia, and clubbed fingers and toes.—In the group of cases in which the venous-arterial shunt is transitory, depending on temporarily induced increased pressure on the venous side, there frequently is a history of episodes of dyspnea or cyanosis. A rather unique feature relative to the cyanosis of congenital heart disease is the absence of edema when the cyanosis is quite pronounced.

Any unusual heart contour in the roentgenogram, such as a prominent pulmonary artery.—Points readily overlooked are: lack of prominence of the aortic knob; shadows to the right of the sternum running up toward the right sternoclavicular joint, as is seen in persistent right aortic arch, and erosion of ribs, which may in itself be diagnostic of coarctation of the aorta. These features are often better elicited by fluoroscopy.

Hypertension.—In a young individual hypertension should lead one to examine the strength of the pulsation in the abdominal aorta and femoral arteries and to look for other evidence to exclude or confirm the presence of coarctation of the aorta.

A cerebrovascular accident in a young person should raise the question of a ruptured aneurysm of the circle of Willis in association with coarctation of the aorta.

Congenital anomalies.—Congenital anomalies in any part of the body should lead one to examine carefully for cardiac anomalies. In Abbott's series,[1] 18.8 per cent of patients had anomalies elsewhere. Mongolian idiots, too, are prone to have congenital cardiac lesions.

Subacute bacterial endocarditis.—This frequently occurs as a complication of congenital heart disease.

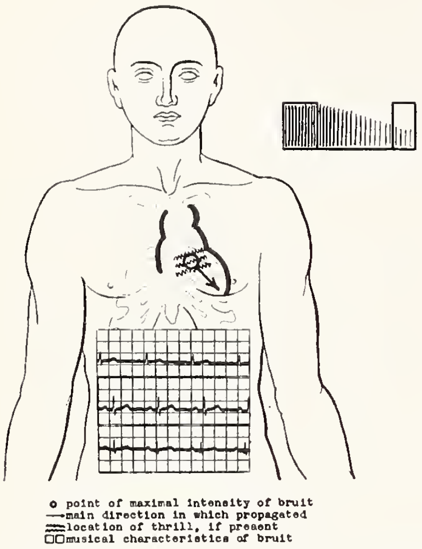
Comment.—When the presence of a congenital cardiac anomaly is suspected, a search should be made for collateral evidence. The murmurs of congenital heart disease are frequently known to have been present since birth. A careful physical examination, a study of the contours of the heart, if necessary, by roentgenoscopy, and a study of the electrocardiographic pattern will contribute the necessary evidence for making a differential diagnosis. Once an anatomic diagnosis has been arrived at, the resultant physiologic mechanism should be reasoned out and checked against the physical findings. For instance, should a loud systolic murmur, best heard over the pulmonic area, lead to the conclusion that a patent ductus arteriosus is present, this opinion should most definitely be revised if the electrocardiogram shows left axis deviation, since this is exactly the opposite of what is consistent with such a diagnosis.

Finally, statistical evidence with reference to the frequency of different congenital lesions will serve to avoid diagnostic errors. Thus, a diagnosis of pulmonic stenosis is made far more frequently than its actual incidence, especially as an isolated lesion.

The Electrocardiogram in Congenital Heart Disease

If one can divorce from one's mind the idea that congenital heart disease is an entity separate from heart disease in general and adheres to the physical principles governing electrocardiography, the subject becomes much more clearly understood. With the single exception of dextrocardia with complete situs transversus, there are no diagnostic electrocardiographic patterns in congenital anomalies. The information so obtained serves merely as one link in the chain of evidence.

Again I must refer to the physiologic alterations concerned in any particular anomaly. If the condition is such as to throw added strain on the left ventricle, as in coarctation of the aorta or subaortic stenosis, a left axis deviation in the electrocardiogram will reflect such a condition as eloquently as it does in arterial hypertension or in acquired aortic disease. If myocardial changes result as a consequence, T-wave changes in leads I and II can be expected to follow.[5] It so happens that the majority of congenital defects are attended sooner or later by strain on the right side of the heart, either because of arteriovenous shunts or stenotic pulmonary effects. Corresponding roughly to the degree, there will be right axis deviation and perhaps T-wave alterations in leads II and III.[5] P waves may be exaggerated, as in acquired mitral stenosis, indicating greater auricular activity.



o point of maximal intensity of bruit
→ main direction in which propagated
≡ location of thrill, if present
☐☐ musical characteristics of bruit

Fig. 4. Interventricular septal defect. The heart contour is normal and the electrocardiogram is normal.

Conduction interferences are at times of considerable diagnostic help when caused by interventricular septal defects, while coronary types of T-wave changes have been noted when the coronary vessels originated from the pulmonary artery.[12]

Auricular fibrillation is very unusual except in a widely patent foramen ovale accompanied by distention of the right auricle.

Very meager information is forthcoming from the literature regarding the fourth lead in cases of congenital heart disease. Of the cases in which a diagnosis of congenital heart disease was made, a fourth lead (Wolferth) was recorded in seventeen. The frequency of abnormal changes is indicated in Table II. It is apparent again that such changes are not in any sense diagnostic but seem to be associated with a cardiac mechanism which throws an added strain on the right side of the heart, particularly if the strain is pronounced or of long standing.

A group of twenty-six cases reported by Edeiken, Wolferth and Wood,[8] in which the fourth lead showed the only electrocardiographic abnormality, included one congenital anomaly. The fourth lead was upright in this case and it was associated with right ventricular preponderance "to the extent of +128°."

The Diagnostic Features of Individual Congenital Anomalies

Interventricular septal defect (maladie de Roger).—Mechanism. There is an arteriovenous shunt because of the higher pressure in the left ventricle. With a failing left ventricle, or with increased pressure on the right side of the heart, the flow is reversed and under these conditions only does cyanosis occur.

The syndrome (Fig. 4). The bruit and the thrill are the important findings. Roger's original description[9] of the bruit has already been commented on. It is best heard in the third and fourth left interspaces and is conducted toward the apex. The second pulmonic sound is not accentuated. The heart's shape has been described as being globular but in the majority of cases it is normal, as is the electrocardiogram. Occasionally, however, there is evidence of interference with the conductive system. Symptoms are absent, but subacute bacterial endocarditis is a frequent complication.

Interauricular septal defect (widely patent foramen ovale).—Mechanism. The shunt again is arteriovenous until conditions arise which cause a reversal of pressures. Cyanosis is thus a frequent terminal event.

The syndrome. Until such events as just described occur, there are generally no signs or symptoms, no cardiac enlargement or abnormal contour features, and the condition may thus remain unsuspected and undiagnosed. A patent foramen ovale should be suspected when (1) there is a history of cyanotic spells or undue cyanosis during pulmonary infections, and (2) when systolic or presystolic bruits, with or without thrills, are audible over the upper portion of the sternum and are not otherwise explainable.

TABLE II. A RECORD OF FOURTH LEADS IN CASES OF CONGENITAL HEART DISEASE

Case	Age, years	Clinical diagnosis	Axis deviation	Fourth lead (Wolferth)	Cardiac symptoms	Comment
1	22?	Auricular septal defect and mitral stenosis	Marked R.V.P.*	Upright T wave Absent R wave	Early decompensation with cyanosis and clubbing	Exaggerated P_2 and P_3 waves
2	45	Patent ductus arteriosus and patent interventricular septum	R.V.P. (despite the presence of a superimposed hypertension)	Diphasic T wave Absent Q wave	Decompensation	Exaggerated P_2 and P_3; diphasic T_2 and T_3; delayed A-V conduction
3	22	Auricular septal defect and patent ductus arteriosus	Marked R.V.P.	Upright T wave	Early decompensation	Exaggerated P_2 and P_3
4	41	Patent ductus arteriosus with mitral and aortic endocarditis	R.V.P.	Upright T wave with elevated R-T segment	Early decompensation	Auricular fibrillation
5	27	Patent ductus arteriosus	R.V.P.	Diphasic T wave	Absent	
6	37	Patent ductus arteriosus	R.V.P.	Normal	Absent	
7	16	Ventricular septal defect	No preponderance	Normal	Absent	
8	61	Patent ductus arteriosus	R.V.P.	Normal	Absent	
9	45?	Ventricular septal defect	No preponderance	Normal	Absent	
10	23	Patent ductus arteriosus	No preponderance	Normal	Absent	
11	25	Ventricular septal defect	No preponderance	Normal	Absent	
12	52	Auricular septal defect with mitral stenosis	R.V.P.	Isoelectric T wave	Decompensation	Auricular fibrillation
13	24	Patent ductus arteriosus	R.V.P.	Normal	Absent	
14	20	Ventricular septal defect with patent ductus arteriosus	R.V.P.	Huge inverted T wave	Poor cardiac reserve	Inverted T_2 and T_3; incomplete bundle branch block; auricular fibrillation
15	19	Patent ductus arteriosus with ventricular septal defect	R.V.P.	Slight depression of R-T segment	Dyspnea on exertion	
16	27	Patent ductus arteriosus	No preponderance	Normal	Absent	
17	19	Ventricular septal defect	Marked R.V.P.	Deeply inverted T wave "M" notching of QRS with diminished Q and exaggerated S wave.	Dyspnea on exertion Cyanosis and clubbing present	Exaggerated P_2. Incomplete bundle branch block. Inverted T_2 and T_3.

*Right ventricular preponderance.

When symptoms do occur, there is usually evidence of right ventricular hypertrophy with enlargement of the pulmonary artery and also of the right auricle. The roentgenologic and electrocardiographic findings will then be in keeping with such events.

Comment.—Among congenital heart lesions, a widely patent foramen ovale is the only one which at times terminates in auricular fibrillation. Paradoxical embolism may occur, but subacute bacterial endocarditis is a rare complication.

Lutembacher's disease (mitral stenosis and interauricular septal defect).—Mechanism. Something of a vicious circle is created by the fact that an easier egress exists through the interauricular septal defect for the blood in the left auricle than through the stenosed mitral orifice (Fig. 5). This means that blood already aërated reaches the right side of the heart, to be sent to the lungs again. While this is no special disadvantage at first, the right ventricle soon hypertrophies, and when it fails, as it inevitably does, a reversal of blood eventually results from the right side of the heart to the left, and cyanosis develops. As decompensation is controlled the degree of cyanosis decreases.

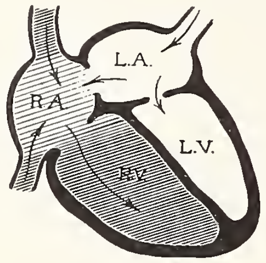


Fig. 5. Lutembacher's disease (patulous foramen ovale with mitral stenosis).

The syndrome. The syndrome consists of: (1) the auscultatory findings of mitral stenosis at the apex, (2) at times, a high pitched bruit audible over the upper portion of the sternum accompanied by a thrill (in a recent case the correct diagnosis was arrived at by this finding), (3) roentgenologic evidence of cardiac hypertrophy; especially affecting the right ventricle, a prominent pulmonary conus and an enlarged right auricle; the aortic knob is smaller than normal, and the pulmonary vessels may be so increased in prominence as to simulate pathologic mediastinal lymph nodes (Fig. 6) (in the case just referred to the preliminary diagnosis was mitral stenosis and Hodgkin's disease), and (4) marked right axis deviation in the electrocardiogram.

Comment.—Right heart failure eventually results.

Subaortic stenosis.—Mechanism. The mechanism is the same as in acquired aortic stenosis.

The syndrome. The syndrome consists of: (1) a harsh systolic bruit at the base transmitted to the vessels in the neck, (2) an accompanying thrill, (3) forceful action of the left ventricle in contrast to a weak radial pulse, (4) absence of symptoms, and (5) evidence of left ventricular strain roentgenologically as well as electrocardiographically (Fig. 7).

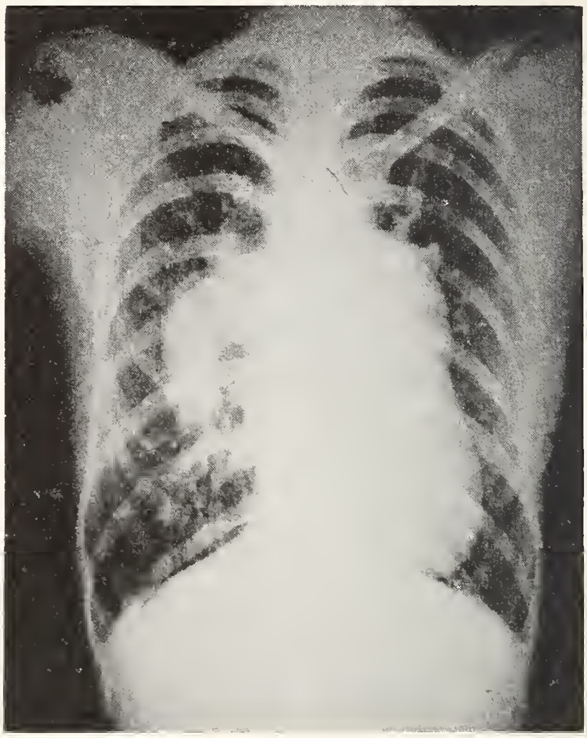

Fig. 6. Roentgenologic appearance of Lutembacher's disease, showing the enormous dilatation of the pulmonary vessels (simulating a mediastinal tumor) and the rounded apex, representing a much hypertrophied right ventricle.

Comment.—The prognosis is good.

Pulmonary stenosis.—Mechanism. (1) With a closed interventricular septum, the right ventricle naturally hypertrophies markedly. Depending on the degree of the defect, cyanosis almost inevitably supervenes, although the individual may reach adult life before it becomes noticeable. Once it begins, it is likely to be progressive, with increasing clubbing and polycythemia. (2) With an interventricular septal defect (which is far more common), the load is taken off the right ventricle to some extent, but cyanosis occurs earlier because of the venous-arterial shunt. In both instances the foramen ovale is likely to be patent, no doubt, because of increased pressure on the right side of the heart; this may add to the venous-arterial shunt.

The syndrome. The syndrome consists of: (1) A harsh systolic bruit in the second left interspace, which is transmitted toward the left shoulder and not to the vessels in the neck, (2) a well-marked thrill, (3) a prominent conus, and enlargement of the right auricle, (4) right ventricular strain electrocardiographically, and there may be T-wave changes in leads II and III significant of right heart strain, and (5) cyanosis, sooner or later, with the usual secondary manifestations (Fig. 8).

≡location of thrill, if present
□□musical characteristics of bruit

Fig. 8. Pulmonary stenosis, showing the prominence of the conus shadow and the hypertrophied right ventricle. The electrocardiogram shows right axis deviation. The shading of the lips indicates cyanosis.

Comment.—Symptoms tend to develop early. Dyspnea on exertion heralds the manifestations associated with impaired oxygenation and myocardial damage. Not a few patients succumb to subacute bacterial endocarditis.

The tetralogy of Fallot.—Mechanism. As the right ventricle empties itself, the smaller portion of venous blood enters the much narrowed pulmonary artery, whereas the major portion enters the large aorta, which usually directly overrides the defect in the interventricular septum (Fig. 2). The venous blood which does get aërated returns to the left auricle and so to the left ventricle. With contraction of the latter, this aërated blood joins the stream of venous blood from the right ventricle in the aorta. It is apparent, then, that with the combined effects of the venous-arterial shunt and the much restricted pulmonary circulation, cyanosis will be prominent. The peribronchial vessels help, to a greater or lesser degree, to carry blood for aëration to the lungs, and the efficiency of this alternate route does a good deal toward establishing the prognosis in the individual case.

The syndrome. The syndrome is as follows: (1) Cyanosis tends to begin early in life and often becomes extreme, (2) bruits may be absent, but there is usually a systolic murmur at the base transmitted to the vessels in the neck, with or without an accompanying thrill, (3) the heart becomes sabot-shaped because of the prominent right ventricle without enlargement of the pulmonary artery, and because of the dextroposition of the aorta, the great vessels will be prominent on the right, and (4) there is electrocardiographic evidence of right ventricular strain (Fig. 9).

Patent ductus arteriosus.—Mechanism. Because of the higher aortic pressure, blood is shunted from the aorta into the pulmonary artery. While this is not particularly disadvantageous, it does increase the load on the right ventricle. When conditions arise which increase the pressure in the pulmonary circuit above that in the systemic circulation, a reversal of the shunt occurs, with cyanosis corresponding in degree and duration to the extent of the shunt.

The syndrome. The syndrome consists of: (1) A "machinery" or continuous murmur in the second left interspace which is transmitted toward the left shoulder, the second pulmonic sound usually being accentuated, (2) dulness in the region of the second and third left interspaces (Gerhardt's ribbon dulness), (3) a prominent conus shadow, and (4) right axis deviation in the electrocardiogram (Fig. 10).

Comment.—This is a typical example of a congenital lesion in which symptoms are absent in marked contrast to the prominent physical findings. The frequent development of subacute bacterial endocarditis renders the prognosis guarded, even though no serious mechanical difficulties are likely to develop.

location of thrill, if present
musical characteristics of bruit

Fig. 10. Patent ductus arteriosus (Botalli). Note the prominence of the conus shadow. The electrocardiogram shows right axis deviation.

Coarctation of the aorta.—Mechanism. The obstruction to the aorta is usually just beyond the origin of the left subclavian artery, that is, at or near the junction of the ligamentum arteriosum and the aorta. The ligamentum arteriosum is the occluded ductus arteriosus, and it often remains patent when anomalies of the aortic arches are present. Interference with circulation beyond the point of obstruction depends (1) on the degree of coarctation, and (2) on the degree of collateral circulation which can be built up. The latter element, affecting mainly the intercostal arteries and the internal mammary artery and its branches, gives rise to characteristic clinical and roentgenologic findings in the form of pulsating vessels and erosion of the undersurface of some of the ribs (Fig. 11). The obstruction also results in increased pressure in the vessels arising proximal to the point of obstruction. In these cases pulsations in the abdominal aorta and femoral vessels are markedly diminished in contrast to hypertension in the upper extremities.

The syndrome. The syndrome is as follows: (1) a systolic bruit is often present over the base and is easily confused with acquired aortic stenosis, (2) a thrill may accompany the bruit, (3) there is evidence of left ventricular hypertrophy, (4) there is electrocardiographic evidence of left ventricular strain, and (5) there is evidence of the collateral circulation just described.

Comment.—Coarctation of the aorta may be latent for years, and congestive heart failure may first bring the patient to a physician. Very frequently, however, the condition terminates fatally as a result of the development of subacute bacterial endocarditis, and not a few patients die suddenly from a ruptured aneurysm of the circle of Willis, which is frequently an associated congenital anomaly. Many patients complain that their legs "go to sleep" very readily because of diminished circulation to the lower extremities. Others live to an advanced age and die from an unrelated cause.

Persistent right aortic arch.—Mechanism. Physiologically, the mechanism is perfectly normal and represents the avian arrangement. The abnormal anatomic situation, however, especially its relation to the trachea and esophagus, may cause symptoms of pressure referable to these structures.

The syndrome. The syndrome consists of (1) evidence that the ascending aorta is further to the right than normal, namely, dulness to the right of the sternum, pulsation in the second or third right interspaces, maximal intensity of the aortic heart sounds to the right and above the usual location, and strong pulsations in the right supraclavicular fossa; and (2) characteristic roentgenologic findings, which are (a) a shadow to the right of the sternum running upward toward the right sternoclavicular joint, (b) evidence of displacement of the esophagus and trachea toward the left (this is well brought out by fluoroscopy with a barium-filled esophagus, whereas a stomach tube may be delayed at the point of displacement and transmit the pulsation from the arch of the aorta), (c) absence of the normal aortic knob in the usual situation and the presence of a retro-esophageal aortic knob determined by fluoroscopy, and (d) corroborative evidence is supplied by eliciting, fluoroscopically, a diverticulum-like structure joining the descending aorta which represents the fourth left arch beyond the point of origin of the ductus arteriosus (Fig. 3).

Comment.—In most of the cases described, the heart is normal and symptoms may be entirely absent. So-called dysphagia lusoria resulting from esophageal displacement occurs but is frequently absent as in Arkin's[3] cases.

Congenital anomalies which are rare but in which the diagnosis may be suspected.—Anomalies of the coronary artery. McGinn and White[7] described the case of an infant who manifested attacks of distress on effort, such as when nursing, while the electrocardiogram showed T-wave changes of the coronary type. The heart was hypertrophied. At necropsy a single coronary artery was found arising from the pulmonary artery. The effects of anoxemia in this case were analogous to those in occlusive coronary disease.

Cor triloculare biatriatum. On the basis of another anomaly the same authors laid down the dictum that when in the roentgenogram a "water-bottle" shaped heart resembling a pericardial effusion is associated with intraventricular conductive disturbances in the electrocardiogram, a three chambered heart of the foregoing type should be kept in mind.

The Prognosis in Congenital Heart Disease

It is not always easy to prognosticate the future course of congenital heart disease. There is, however, with a few reservations, no reason to deviate from the usual criteria for judging cardiac efficiency. The heart is essentially a muscular pump and its main function is to maintain adequate circulation under the varying conditions incident to the daily life of the individual. With this as a premise, and it is common to all cardiac states, and with the general principle common to the wider fields of diagnostic medicine that an isolated sign rarely has much significance, the degree to which this, its main function, is interfered with in the main establishes the prognosis.

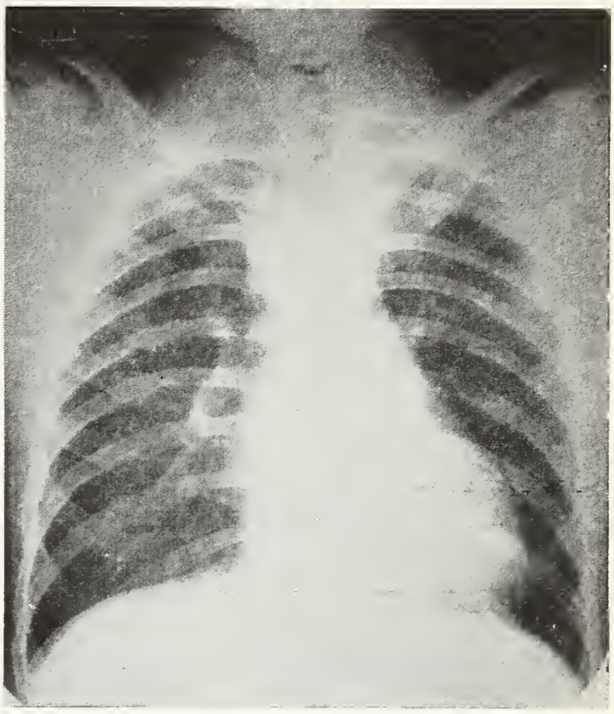

Fig. 11. Roentgenologic appearance of coarctation of the aorta: Note the absence of the aortic knob and the erosion of many of the ribs. The left ventricle is hypertrophied.

The nature and degree of the mechanical disadvantage are the first considerations; hence, again, the importance of establishing an anatomic diagnosis. In states such as patent foramen ovale, patent ductus arteriosus, maladie de Roger, and subaortic stenosis, it may be practically negligible and in spite of loud murmurs there may be little if any interference with the patient's activity. When, however, the degree of altered function is such as to place undue strain on one or more chambers of the heart, hypertrophy, dilatation, and later, loss of cardiac reserve, must inevitably follow. This undue strain is mainly brought about by abnormal shunts of blood through incomplete septa or through stenotic orifices, and finally, through extracardiac factors such as increased pressure within the pulmonary circuit. Evidence of hypertrophy or enlargement of individual chambers or of the heart as a whole then definitely influences the prognosis adversely, according to the degree of such enlargement.

The reservations previously referred to are occasioned by the vulnerability of the congenitally anomalous heart to rheumatic fever, by the frequency with which subacute bacterial endocarditis becomes engrafted upon it, and by the sudden death of an individual in apparently good health. Abbott's statistical studies supply enlightening information regarding the termination in various types of congenital heart disease.[2] Small interventricular septal defects with patent ductus arteriosus may interfere very little with activity, but in from 20 to 25 per cent of cases of both types subacute bacterial endocarditis develops. In contrast, a widely patent foramen ovale is hardly ever the basis for such a complication, but in about half the cases congestive failure eventually develops. For the group of cases in which lesions involve the pulmonary infundibulum, with or without associated ventricular septal defects and the different degrees of transposition of the great vessels, the prognosis is not good. Cyanosis is likely to develop early and to be progressive, and incapacitation is the rule. Subacute bacterial endocarditis terminates life in more than 20 per cent of this group.

The individual with coarctation of the aorta leads an existence beset with even more hazards. About a third of the patients die with congestive failure; subacute bacterial endocarditis claims about 10 per cent. An unexpected and dramatic termination is not infrequently the result of a subarachnoid hemorrhage due to rupture of an aneurysm of the circle of Willis, and rupture of the proximal part of the ascending aorta not infrequently occurs. Of Abbott's seventy patients with the adult type of coarctation, twenty-two died suddenly. Headaches, convulsions and other neurologic complications have been commented on.[15]

In spite of mechanical disadvantages and unpredictable hazards, however, remarkable instances of longevity have been recorded. Thus, Firket's patient,[10] a woman with combined mitral stenosis and an auricular septal defect, went through eleven pregnancies and three abortions and lived to the age of seventy-four. Lutembacher's patient,[11] also a woman and with the same type of lesion, lived to be sixty-one years old and went through seven pregnancies without heart failure, and two other patients with the same types of lesions lived to the age of seventy-four and sixty-two years, respectively.[6] White and Sprague's[14] case of the tetralogy of Fallot was even more remarkable. The patient, although cyanosed, lived a full life and died at the age of fifty-nine years and eight months. Erickson and Willius[9] reported a case of widely patent foramen ovale, so wide that a normal heart could be fitted snugly into the opening; yet the patient, a man, lived to be seventy-one years old.

Summary and Conclusions

A study of the embryology and comparative anatomy of the heart is essential in understanding the genesis and mechanism of human congenital cardiac anomalies. A number of these congenital lesions are recognizable clinically. The syndromes diagnostic or suggestive of interventricular and interauricular septal defects, including Lutembacher's disease, subaortic and pulmonary stenosis, the tetralogy of Fallot, patent ductus arteriosus, coarctation of the aorta, persistent right aortic arch, one type of coronary artery anomaly, and the cor biatriatum triloculare have been described.

While electrocardiographic evidence is important in the recognition of congenital heart disease, there is no diagnostic picture for any type except congenital dextrocardia with complete situs transversus.

The uncomplicated septal defects, patency of the ductus arteriosus, subaortic stenosis, and persistent right aortic arch may interfere with activity only to a limited extent, but the frequent occurrence of subacute bacterial endocarditis as a complication renders their prognosis guarded. Occasionally, an individual with a gross cardiac defect lives to an advanced age.

POLYNEURITIS IN CHILDREN*

R. E. CUTTS, M.D.

Minneapolis, Minnesota

THE frequency of recent publications concerning Vitamin B, its components and related substances induced a request for a résumé of peripheral neuritis in children. When I agreed to prepare such a summary, it was my impression that patients suffering from polyneuritis were admitted to the University Hospital fairly frequently, and that a considerable group of case histories could be collected for analysis. This impression proved erroneous. Despite its apparently low incidence among the children of Minnesota, the prolonged and severe disability requiring nursing care, physiotherapy and, in some cases, orthopedic surgery make the condition an important one.

The gross pathology of polyneuritis is usually very minimal although some swelling and congestion of the peripheral nerves may be detected. Microscopic sections prepared with special stains will show disintegration of the medullary sheaths with lipoid deposits within the sheaths. There is usually some evidence of phagocytosis. Spindle shaped enlargements and granular degeneration of the axis cylinders may be seen.

The symptoms of polyneuritis are usually both sensory and motor. The motor symptoms begin with weakness which, in the more severe cases, progresses to flaccid paralysis with impairment or loss of deep reflexes. Sensory symptoms include pain, paresthesia, hypesthesia and less frequently anesthesia. Customarily the lower extremities are first involved with progression to the upper extremities and trunk. The distribution is roughly symmetrical.

General treatment during the active stage consists of supportive measures, elimination of foci and sources of toxin, improvement of nutrition, protection of the weakened muscles and the use of oxygen when the muscles of respiration are involved. As recovery progresses, physiotherapy and orthopedic appliances are usually indicated. Finally, surgery may be required to decrease disability where recovery has been incomplete. Specific measures are indicated where a specific etiology can be determined.

Many factors have been incriminated as etiologically important in the production of polyneuritis and the disease is roughly subdivided according to the supposed etiology.

Metallic poisoning, either accidental or as a result of therapy, accounts for a considerable proportion of these cases. Of the metals, the most frequent offender is lead. Lead may be ingested by children as a result of chewing paint from furniture and toys. Food and water may become contaminated from pipes or containers. Insecticides and sprays are other possible sources. Several children have acquired lead poisoning as a result of collecting foil or from molding toys with small casting sets. Children are infrequently exposed to lead directly from industrial sources but may be indirectly endangered as was the case when battery cases were used for fuel.

Four of the cases of polyneuritis in children admitted to the University Hospital in the past ten years proved to be cases of lead poison. Of these, two resulted from collecting foil. In one case foil was recovered from the feces. The other two were brothers who lived on a farm where a lead spray was used, but the exact mode of ingestion could not be determined. Confirmatory evidence by chemical analysis and by demonstration of a lead line in x-rays of the long bones was present in three of the four cases. In the fourth, positive x-rays were not obtained until approximately a year after the onset of the neuritis. Other findings which sometimes aid in confirming the diagnosis were absent in all four cases. These include anemia, stippling of the erythrocytes and a blue lead line at the gum margin. All four patients were markedly improved at the time they were last heard from.

---

*Read at the annual meeting of the Minnesota State Medical Association, Duluth, Minnesota, July 1, 1938.

The prognosis for complete recovery after lead polyneuritis is not as good as after most types because there is apparently a more marked involvement of the spinal cord. In the cases presenting evidence of lead encephalitis the prognosis is considerably worse.

Special therapy during the active stage is aimed first at removal of the lead from the blood stream and later at removal of the lead from the body. The first is attempted by giving calcium, phosphorus, large doses of vitamin D and alkalies. Removal of the lead from the body is attempted by the use of the ketogenic diet, acids and parathyroid extract.

Arsenic is another metal which is capable of producing polyneuritis. In these cases the source is usually arsenic administered therapeutically either as an antiluetic or as a tonic. Accidental ingestion of rodent poison or insect spray is a less common source. Elimination of arsenic may be hastened by the use of sodium thiosulphate.[1]

Since the substitution of x-ray for thallium as a depilatory, especially in the treatment of ringworm of the scalp, children are infrequently exposed to this metal.

Recently bismuth has been used in place of mercury as an antiluetic and a few cases of polyneuritis from this source have been reported. They closely resemble the polyneuritis of lead and produce the same x-ray findings.

Cases of polyneuritis due to or associated with infections are less readily classified. That following diphtheria is considered the most common type in children. Diphtheritic polyneuritis is almost invariably preceded several days by local paralysis such as the paralysis of soft palate and pharynx associated with faucial diphtheria. Neuritis occurs almost exclusively in cases where antitoxin has been administered late or in inadequate dosage. The multiple neuritis usually appears from three to eight weeks after the onset of the disease. Weakness of the extremities with loss of tendon reflexes and tachycardia are the characteristic findings with sensory changes much less prominent. The extremities are most severely involved but neck, trunk and respiratory muscles may also be affected. No cases of diphtheritic polyneuritis have been admitted at the University Hospital in the past ten years. Only once was the diagnosis made at the Minneapolis General Hospital during that period.

A much smaller group of cases has been reported in which the neuritis developed several days after a brief febrile illness of undetermined origin.[9] The polyneuritis in these cases is roughly symmetrical, usually associated with bilateral facial paralysis, frequently affecting proximal muscle groups of the extremities more than the distal groups. The causative organism is unknown and more than one may be responsible. If the acute stage is survived, recovery is usually rapid and complete. One case at the University Hospital may represent this group. Ten days after the rapid development of weakness and paresthesia in arms and legs the patient was markedly improved and after two months his only complaint was that he tired more rapidly when running. Chemical, x-ray and blood tests were all normal at the time of his admission. Interpretation of his spinal fluid examination was obscured by a bloody tap previous to admission.

Periarteritis nodosum is said to be accompanied by polyneuritis in 20 per cent of the cases.[6] It occurs rarely and the neuritic symptoms are likely to be overshadowed by the other symptoms of the disease.

Polyneuritis occasionally complicates other diseases, notably tuberculosis, typhoid, paratyphoid, malaria, septicemia, pyogenic infections, scarlet fever and mumps. Diabetes in children is rarely complicated by polyneuritis. Two of the most frequent causes in adults, chronic alcoholism and pregnancy, are rarely encountered in children.

Some of the cases can only be classified as chronic polyneuritis of unknown origin. These usually develop progressively over a period of months or years until there is almost complete paralysis of the extremities and trunk. Even after this extensive involvement, slow but complete recovery is possible.[2] Two of the cases at the University apparently fall in this group. The history of one is particularly striking. An eight-year-old girl began to complain of pain in the legs and gradually developed a peculiar dermatitis. Weakness of the extremities began to develop after three or four months and progressed until the voluntary muscles below the mandible seemed almost completely paralyzed six months after the onset of the illness. For one week there was considerable difficulty with respiration. Approximately one year after the onset of the illness, while the child was at home, improvement began and continued until she was able to propel a wheel chair after another six months. When an orthopedist examined her six years after the onset of the illness he detected only a slight weakness of one foot for which exercise but no appliance was recommended.

Several drugs other than the metals previously mentioned have been cited as causes of polyneuritis. Among these are dinitrophenol, atabrine, sedatives of the chloral group, and, rarely, anesthetics including ether and novocaine. Occasional cases have been reported following the administration of foreign protein such as therapeutic sera.[12] Hematoporphyrinuria[5] and hematoporphyrin hydrochloride[10] used therapeutically may also cause polyneuritis.

Dietary deficiencies are known to be capable of causing neuritis. Classical beriberi as seen in the Far East and infrequently in the U. S. is the best example of polyneuritis definitely on a dietary basis. Much less frequently, neuritic symptoms may result from restricted therapeutic diets as used for gastro-intestinal disease and food allergy as well as the ketogenic diet, if no allowance is made for an adequate vitamin intake.

Wechsler[11] in 1932 expressed the opinion that vitamin deficiency is necessary for the production of toxic neuritis of obscure origin and is also partially responsible for some cases in which a specific poison is at fault. This may account for individual differences in susceptibility.

Strauss[8] gives one the impression that all types of peripheral neuritis, except those due to diphtheria, those associated with acute febrile disease and those due to exogenous toxins such as lead and arsenic are due to vitamin B deficiency. He believes that pregnancy, chronic infection, alcoholism, etc., provoke polyneuritis by decreasing the intake and absorption of vitamin and increasing the requirement. Spies,[7] Jolliffe,[3] Romano[4] and their co-workers agree that this is the case in polyneuritis of pregnancy and alcoholism.

Until recently, massive doses and parenteral administration of Vitamin B has not been practicable. Since B_1 is now available in pure concentrated form, information should soon be available concerning its use in the less common types of polyneuritis.

Nicotinic acid, which has proved quite effective in the treatment of canine black-tongue, a disease resembling pellagra, and of some of the symptoms of pellagra, seems to be quite ineffective in the treatment of the neuritic symptoms.[7] Whether the components of the B complex other than B_1 are likewise unimportant in the treatment of neuritis and whether large doses of B_1 orally or parenterally will have any beneficial effects in the treatment of polyneuritis following diphtheria, the metallic and drug intoxications remains to be determined.

Discussion

Dr. J. C. McKinley, Minneapolis: Dr. Cutts has presented the important etiologic factors of peripheral neuritis and has assigned vitamin B_1 about the place that seems reasonable at the present stage of its investigation. Because of the variable severity and irregular duration of polyneuritis, it is difficult to assess the value of a single factor without painstaking clinical work under practically experimental conditions.

Most clinicians are unaware of an observation by neuropathologists which may partly explain the greater frequency of polyneuritis in adults as compared with children: namely, the fairly common occurrence with advancing years of arteriosclerosis of the vasa nervorum. Obviously a condition of decreased blood supply to the nerve would predispose to nerve injury on the superimposition of toxin, poison, vitamin deficiency or what not. This condition is being given detailed study at the present time in our Neuropathology Laboratory at the University of Minnesota.

WHAT IS NEW IN THE FIELD OF FOOD-SENSITIVENESS*

WALTER C. ALVAREZ, M.D.
Rochester, Minnesota

I HAVE been asked to tell you today of what's new in the field of food-sensitiveness. I use the word sensitiveness and not allergy because I feel so sure that food-sensitiveness is not always due to allergy; much of it is due to irritant or slightly emetic drug-like substances.

The first point I want to make is that in spite of doubt, amusement, and apathy in some quarters, the recognition of the importance of food-sensitiveness in the production of many puzzling syndromes is now spreading rapidly through the profession. In fact, interest has already reached that to-be-expected stage in which some men are so enthusiastic that they are seeing "food allergy" everywhere, and are beginning to starve their patients right and left.

Actually, the subject of food-sensitiveness must be of interest to everyone in medicine because one in every four dyspeptics is sensitive to at least one food, because specific reactions to food can upset the functions of so many of the organs of the body, and because every so often the physician can work a miracle by removing one or more articles from a patient's diet.

The physician is particularly likely to forget food-sensitiveness or to pooh-pooh the idea that this might be the cause of symptoms when he is dealing with a thin, frail, neurotic woman with a lot of curious aches and pains. It is so easy, and generally so sensible, to assume that all these symptoms are due to nervousness, fussiness, and constitutional inadequacy, but occasionally the physician will be wrong as I was awhile ago. For weeks I struggled in vain to help a thin, nervous woman who, in spite of everything I did, went on losing weight and having one migrainous headache after another. She had told me that she suspected that she was so sensitive to milk that she couldn't even touch butter, but since in years I had seen but two or three patients as sensitive as that, I had taken the statement with a large grain of salt, as we physicians so commonly do when a story does not hang together very well. Finally, in desperation, when my usual elimination diets did not help, I acted on her suggestion and removed every trace of milk and butter from her food, whereupon she lost her headache and misery and depression, and began to gain steadily in strength and comfort. Actually, it appears now that she can stand a fairly liberal diet so long as every trace of milk is kept out of the food. Even her bread has to be made without milk.

The Trouble Is Not in the Patient's Head

Now, a few years ago, I would have said, as some of you are thinking right now, that this sort of thing is in the patient's head, and that a physician who can believe such tales must also have something wrong with *his* head, but after the miracles of healing that I have seen in the last few years and after the remarkable improvement in my own bodily comfort that has come since I discovered the several decided sensitivenesses to food which, unrecognized, hounded me for most of my life, I am prepared for anything.

One must admit that the trouble is not in the patient's head when one learns that every so often, in spite of all his efforts to avoid his bête noir, he gets a bad upset due to eating the offending substance well concealed in other foods. For instance, a patient who knows of his great sensitiveness to chicken could not be hired to eat a piece of the meat, but for awhile after the discovery of the cause of his attacks of bloating, diarrhea, and mental depression he kept getting upset occasionally with the well-known syndrome, and each time a little detective work showed that the harmless-looking cream soup he had eaten for dinner had been made with chicken stock. He knows now that he must not even taste a soup of doubtful origin, because if it be made from chicken, two tablespoonfuls are enough to give him abdominal pain, a restless night and a headache next day.

Other patients who are highly sensitive, to, let us say, cottonseed oil, when away from home do not dare to touch anything fried, or any pastry made with shortening, or any salad with a dressing. They cannot recognize the nature of the fat used by its taste, and when a few hours later, the retching starts, it is too late to do anything about it. No, the trouble is not in their heads.

---

*From the Division of Medicine, The Mayo Clinic, Rochester, Minnesota. Read before the annual meeting of the Minnesota State Medical Association, Duluth, June 30, 1938.

Two Problems Today

Curiously there are two big problems today in the field of food-sensitiveness: one is to get more physicians to wake up to the importance of the subject, and to keep on the watch for patients whose indigestion, headache, or mental hebetude is due to the eating of some food; and the other is to keep a few physicians from becoming so enthusiastic over the miracles that they have performed that they will starve patients unjustifiably, and for too long a time. Every so often now I see persons who have lost anywhere from *20* to *60* pounds in weight from having been left too long on either an elimination diet or a diet lacking a score of important foods. Usually the eating of these foods was forbidden simply because the skin happened to react to them; a little testing would have shown that these reactions had no significance and that the patient's symptoms were not due to the eating of any of the foods.

Skin Tests

Actually, no one should trust skin tests so implicitly. They are of considerable value in the search for the causes of hay fever, asthma and eczema, but commonly they are useless in the search for the causes of abdominal distress and headache. They are of so little value that we at The Mayo Clinic seldom use them for this purpose unless we are desperately in need of a hint, or we fear that if we do not use them a much-traveled and doctored patient will think we were negligent. Often the tests are nothing but a nuisance as when a fussy woman who has seen that her skin responded to certain foods, refuses ever to touch them again. Actually, no one should ever stop eating a food simply because the skin on one occasion reacted to it with a little wheal. One should reject a food only when it is found, on repeated trials, that every time it is eaten distress follows.

But if the skin tests are of little value, what is one to use? How about the leukopenic index: the test in which the leukocyte count goes down when the offending food is eaten? My impression is that this is too time-consuming and expensive for ordinary use. Furthermore, unless the counts are made most carefully with the patient under basal conditions, the conclusions drawn are likely to be erroneous. As Garrey has shown, the leukocyte count varies markedly from hour to hour during the day, and worse yet, there is no such thing as an errorless count. Even the most practiced girl cannot get five counts on the same blood to come out the same.

The Diary Method

I prefer to use two methods which are simple, practical and inexpensive, and likely to give conclusive results. When the indigestion or pain or headache comes in attacks at intervals of days or weeks or months, the best way of finding the offending food, granting that there is one, is to have the patient make each time a record of the unusual foods—not eaten every day—consumed in the twelve hours preceding the upset. Most suspicion should fall on food eaten at the preceding meal, because in most cases distress follows within a few hours after the eating of an injurious substance.

Most patients in trying to keep a diary make the mistake of putting down everything they eat, with the result that they pile up such a mass of data that they cannot learn anything from it. If, for example, a man gets his distress some day just before noon it will be silly to make note of orange juice, toast, and coffee if these are the foods eaten for breakfast day after day, when no symptoms follow. But, if on the particular morning the man broke his usual custom and drank chocolate instead of coffee, that is something to make note of.

After the patient has suffered three or four attacks the record should be examined to see if there was any one food eaten before each upset, and followed by distress every time it was eaten. If such a food is identified, it should then be left alone for awhile to see if the patient remains well. If relief is obtained, then the food should be eaten again and tested at least twice to see if its ingestion always brings an attack. If it does, this food should obviously be crossed off of the person's diet list. If it should be a food commonly used, like milk or egg, then the patient should make a study to see if he can take small amounts at intervals, or if he is so sensitive that he must not touch cake, puddings, and other foods containing milk and egg.

It is well that the patient in the diary make note, also, of any unusual fatiguing or upsetting incident that occurred before an attack, or of severe constipation, or the coming of a migrainous headache, menstruation, or a cold. Often such happenings are more productive of the symptoms than are changes in diet.

The Elimination Method

When the distress that the patient complains of is present every day, the problem of finding the offending food or foods must be simplified by reducing the number of possibilities. To do this I generally ask the patient to eat *nothing* for two days but lamb, rice, butter, sugar, and canned pears. I use these foods because I know from experience that they seldom cause trouble even in highly sensitive people. Occasionally, when the patient assures me that when he lives on nothing but buttermilk, or, let us say, beef, asparagus and string beans, he is well, I gladly start with those foods as an "elimination diet." The battle is all but won as soon as *any diet* is found on which the patient will lose his symptoms.

Every month I see highly allergic patients who searched for offending substances in the diet and failed to find them, usually because they were unwise in their choice of foods for the first elimination diet. Thus, I recently saw a woman who started off with milk and custards, which was about as bad a choice as could have been made because milk and eggs are among the commonest of offending substances. Worse yet, she kept on hopefully with this diet for a month in spite of the fact that none of the symptoms cleared up. Other patients fail in their search because their method is to give up first one food and then another. Since most food-sensitive persons have trouble with several articles of diet, it is obvious that this plan of eliminating one food at a time will seldom yield any information.

Usually, if the patient's troubles are due to food-sensitiveness, and the elimination diet used happens not to contain any of his particular offenders he returns *next day* to announce that the soreness and gas have gone out of his bowel, and his head feels clear again. Especially when the patient volunteers the statement that his head feels right again, I know that I have eliminated some injurious food, and I am almost certain that I am going to work a cure. All that remains then to be done is to add a food a day, testing one after another until all the offenders are found.

Usually I start testing foods that are not very common offenders because I don't want to begin by upsetting the patient and discouraging him, and especially if there has been great loss of weight, I want him to gain a little before I start "rocking the boat." Usually I begin by adding foods such as gelatin, carrots, asparagus, string beans, rye krisp, arrowroot cookies, turnips, potato, beef, apple sauce with tapioca or sago, and thin, well dextrinized toast. As soon as the patient has gained confidence and is satisfied that his trouble is due to food-sensitiveness he can begin to experiment with such common offenders as milk, chocolate, egg, and coffee.

If, however, the patient does not, in twenty-four or forty-eight hours, improve on the elimination diet of lamb, rice, butter, sugar and pears, the physician must *immediately* face two possibilities: either the patient's troubles are not due to food-sensitiveness, or else they are due to the eating of one or more of the five foods supplied. Oftentimes in the two days of observation a woman will show herself decidedly unreasonable and cantankerous; she will fuss and complain bitterly of her deprivations, or she will cheat or refuse to coöperate, or it will come out that the trouble with her is that she can't stand the appearance or the smell of the food, or that she becomes nauseated if it looks greasy, or that she becomes ill the minute she eats. The physician will then be almost certain that he is dealing primarily with either a nervous hypersensitive person, or a spoiled, undisciplined fuss-budget, or someone with but little gray matter between her ears. This, of course, is most helpful information because it will show the physician right off that he is never going to find any diet that will help, and he might as well stop wasting his time. The obtaining of such valuable information so quickly is one of the most useful features of the elimination type of diet, and one that, so far as I know, no one has as yet mentioned. This ability of the diet to unmask immediately overly nervous, psychopathic and uncoöperative patients should cause it to be used daily even by those men who do not believe in food-sensitiveness. In other cases the failure of an elimination diet to help a women with a sore, gassy abdomen will strengthen the physician's suspicion that the trouble is due to an inflammation of the gallbladder.

But to get back: if the patient appears to be sensible, and the symptoms and history strongly suggest an allergic disturbance, the physician will not give up but will try another simple elimination diet consisting, let us say, of beef, asparagus, string beans and gelatin. If this doesn't help in two days the chances are that the trouble is not due to any food. However, if the physician still thinks the symptoms should be allergic in origin and due to food, he can ask the patient to take nothing but water or only a little maple sugar for forty-eight hours. Then, if the discomfort persists, it is hardly likely that it is due to a food, and the patient might as well go back to a full diet.

The point that I would like now to hammer home is that an elimination diet is to be used for diagnosis and not for long-continued treatment. Occasionally a woman will be so delighted with the relief obtained on an elimination diet she will go back home, content to live indefinitely on her five foods, or if she does report back to her physician, it will be hard to get her to try any new ones. Usually, however, she is glad to have a wider choice, and always she must be helped to get back onto as full a diet as she can tolerate.

There is one group of persons who may have to be kept for several weeks on an elimination diet before one can be sure of the effect, and this is the group of patients with migrainous headaches who have only one or two a month. They should be given a little more liberal list so that they can maintain nutrition and not get too disgusted with the foods eaten day after day. In such cases Rowe's diets are helpful.

The Problem of Persons Highly Sensitive to Many Foods

Unfortunately, there are some persons who are so sensitive to so large a number of the common foods that the physician must make a big effort to supply substitutes and sufficient vitamins and calcium. Unfortunately, in our newly aroused enthusiasm for allergy, some of us physicians are doing today with foods what we for long have been doing with teeth: day after day we order teeth removed but we seldom bother to see to it that the patient puts back bridges or plates. Today foods are blithely being taken away from patients, without even a suggestion as to possible substitutions.

We physicians should be making a greater effort to help all highly food-sensitive persons, and especially those harrassed mothers who have to bring up asthmatic children that cannot touch many of the commonly used foods. A few allergists located in large cities are now inducing one or more bakers to prepare breadstuffs without wheat, milk or egg, and doubtless before long such foods will be prepared for shipment to patients everywhere.

There is need also for better labeling of foods. How, for instance, is a wheat-milk-sensitive person going to know whether or not he can eat an "arrowroot cookie"? Does it contain a little wheat and perhaps a little milk or does it not? Or how is the person tremendously sensitive to cottonseed oil going to know for certain that the "olive oil" he buys will not start him to retching when he puts a little on his salad?

The Need for Searching the Food Markets of the World

For those few persons who are highly sensitive to many foods we physicians must reach out into foreign countries to find substitutes: foods to which the man should theoretically not be sensitized because he never ate them before. Unfortunately highly sensitive persons will react badly to foods that they probably never ate before, but some harmless ones are likely to be found during the search. Particularly useful are some of the foods that constitute the "staff of life" for peoples in other countries. Probably the best is rice; it has no distinctive taste, and most persons can eat it daily without tiring too much of it. Other good starchy foods to try are barley, oats, rye, millet, lima beans, sago, and the several types of tapioca and arrowroot. Incidentally, I have solved the puzzle of how to give sago, tapioca and arrowroot without milk or eggs by having these starches cooked in apple sauce or mutton broth. Raw apples stand very high in the list of offending substances, but cooked apple seems seldom to give trouble. It is possible that a flour glutinous enough to serve as a binder in baking rice flour could be made from the banana, or from taro—that big starchy tuber which used to be the principal source of food in many parts of Polynesia. Taro flour, which makes a good tasty breakfast mush, is now being canned in Hawaii, and it should be a boon to many food-sensitive persons.

An excellent source of protein, carbohydrate, and fat is the tasty garbanzo or chick pea, which is a great favorite in Spain. The soy bean is good because it contains protein, carbohydrate and fat. Fortunately a way has now been found of removing its unpleasant taste. Dates supply much of the nourishment of the Arab. The avocado or alligator pear is now being raised cheaply in this country, and it can supply much needed fat to some patients. Persons highly sensitive to corn oil or cottonseed oil or to butter might try out a number of the oils that are derived from certain seeds such as sesame and rape.

A new science of world-wide dietetics remains to be opened up, and the day is coming when some grocery stores will carry a special line of unusual foods for the highly allergic person. Every minor constituent of these foods will be stated on the label, and the product will be guaranteed by the manufacturer to be exactly as stated. At present the food-sensitive person who lives in a large city can often enlarge his diet by going down into the foreign quarter and rummaging through the stores which supply immigrants with the foods eaten in their respective countries. In this way one of my badly starved, highly allergic patients obtained dried lichi nuts and chestnut flour from China, big fava beans and garbanzos from Spain, cassava flour from Africa or Brazil, and soy beans from Manchuria, all of which have been life-savers to her. When she came to me, she was living on only two foods and was down to skin and bones.

The Need for Taking Foods in Rotation

There is another helpful suggestion that I can make to the highly sensitive person, and that is to take in rotation the few foods that he can still eat. He must remember, first, that he is more easily sensitized to new substances than are most persons, and second, that whenever he finds some new food that works well, he is likely to eat it in such large quantities every day that he can hardly help becoming sensitized to it. As a result he soon is back where he was before, on starvation rations. Some time ago one such patient, who was nearly at the end of her rope and facing starvation, wrote me that she had solved her problem by taking in rotation a number of foods to which she was only slightly sensitive. By partaking of each food only once in ten days she didn't suffer much, and she did not increase her sensitiveness to the foods. I have since found this procedure very helpful. Fortunately, many persons so sensitive to, let us say, eggs, that they cannot take one every day without getting into serious trouble, can eat one occasionally with only slight discomfort.

Another new science awaits development and that is the science of so treating foods chemically that the harmful substances will be "denatured" and rendered innocuous to sensitive persons. Here is a chance for some young chemist who would like to be another Pasteur; the field awaits him.

Summary

Food-sensitiveness is common enough and important enough so that physicians practicing in many fields must be on the watch for it. It can be the cause of the symptoms even in neurotic and constitutionally inadequate persons. The trouble is certainly not in the patient's head. He has it before he even thinks it is due to food, and every so often he is poisoned by inadvertently eating his offending substance concealed in other foods.

Skin tests are seldom of much value in finding the offending foods. One must not trust them but must test each food by having the patient eat it.

When the upsets come at intervals the patient must keep a record of *unusual* foods eaten before the symptoms appear. If some one food is found to have been eaten before each attack it should be tested several times to see if it always causes the trouble. It should then be avoided to see if without it the patient can remain well.

If the distress is present every day a narrow elimination type of diet must be used. If on this the patient becomes comfortable, one food after another must be tried until the offenders are found and eliminated. If after a day or two on the elimination diet the patient does not get well, the physician must *immediately* face two possibilities: either the troubles are not due to food-sensitiveness or else they are due to the eating of one or more of the few foods supplied. Often during the two days of testing a patient will show herself so overly fussy or psychopathic or unreasonable or uncoöperative or stupid, that it is obvious that nothing can be gained from further dietary tests.

In other cases it may pay to shift to another simple elimination diet or to have the patient take only water for two days. If then the symptoms persist, it will be obvious they are not due to food.

A few persons are so sensitive that great search must be made through the markets of the world for new foods which they can eat. Some of these foods are described.

Patients who are highly sensitive to many foods should eat in rotation the few that they can still eat so as not to become sensitized to them.

Discussion

Dr. E. M. Rustan, Minneapolis.—I think that Dr. Alvarez has covered a very difficult subject in a most complimentary manner. His experience in these matters makes it possible for him to evaluate the efficacy of the various tests, and his warnings are most timely.

Hypersensitivity to food has received a great deal of attention during the past few years. The reason for this is that specialists, other than allergists, realize and recognize that food may cause symptoms previously inexplicable. Since this has occurred there is enthusiasm, as in any new phase of medicine, which in time disappears, and the true value of the subject remains. A few years ago most food sensitive patients were treated as neurotics by empirical methods of diet and change in environment. It is true that so called "neurotic complaints" are present in a high percentage of these patients, but it appears that as our diagnostic acumen increases the group of patients diagnosed as neurasthenics becomes smaller.

The greatest difficulty confronting the physician, in making a diagnosis of food hypersensitivity, is the interpretaion of the laboratory tests in common use. As the author has stated, skin tests are rarely of value in allergic gastro-intestinal disease or in allergic headaches. The tests are of most value in the atopic diseases, but their interpretation always depends upon the individual experience of the physician. Passive transfer tests, when positive, are of importance. However, in adults a strong reactor is oftentimes known to be the cause of symptoms. Leukopenic index tests may be used to a great advantage in some conditions. In many instances the combined results of all the laboratory tests give no specific information, and because of this the patient and the physician are oftentimes misled. Skin tests, leukopenic index tests, and passive transfer reactions do not determine the allergic status of the patient, and should be used only as aids in diagnosis.

After the food sensitivity has been proven, the management of these patients also presents difficulties. Dr. Alvarez has brought this out very graphically and he has emphasized the need for careful study, not only of the individual foods but also of the other foods that may be substituted. Avoidance of the causative agent or agents is the simplest manner of treatment in the majority of instances, as about 50 per cent of these patients may again take foods to which they were sensitive without producing symptoms, after a few weeks or months. Some foods such as wheat, eggs, and milk cannot be avoided because of age, geographical location, and finance. In these instances alteration of the foods by heating or oral hyposensitization is worthy of trial. If this is unsuccessful subcutaneous injection of a properly prepared extract should be tried.

In general the results of treatment depend, to a large extent, upon the physician's knowledge of allergy, and above all else the intelligent coöperation of the patient.

A TYPE OF CHRONIC NERVOUS DEPRESSION IN WOMEN RELIEVED BY THE ADMINISTRATION OF THYROID EXTRACT*

GORDON R. KAMMAN, M.D., F.A.C.P.

Instructor in Nervous and Mental Diseases, University of Minnesota
Saint Paul, Minnesota

THE clinical picture of myxedema with its objective findings of non-pitting edema, swollen face, supraclavicular pads of fat, coarse dry skin, sparse hair, stupid expression, slow movements, the patient's subjective feelings of lassitude, easy fatiguability, loss of initiative, poor memory, impaired concentration, and mental sluggishness is too well known to warrant description here. That an actual psychosis can form part of the clinical picture of myxedema is also well known. Wagner von Jauregg[5] said that 15 per cent of all patients with myxedema have psychoses. Karnosh and Williams[2] in a recent survey of a series of cases were able to corroborate this figure.

The reaction pattern of the psychosis of myxedema is a non-specific one. Ziegler[6] feels that the symptoms evoked by the general physical depression of myxedema are "individual expressions of latent hereditary disposition and constitutional tendency." The most frequent type of true psychosis seen in myxedema is what Adolph Meyer has called the dysergastic reaction. This is a delirious-hallucinatory episode characterized by clouding of consciousness which may extend to complete disorientation, unsystematized delusions of persecution, and excitability. When this reaction appears as one of the clinical manifestations of myxedema it is readily relieved by adequate doses of desiccated thyroid gland. In addition to the dysergastic reaction, other psychotic manifestations may exist as part of the clinical picture of myxedema. Moreover, the psychic manifestations may exhibit themselves before the classical physical appearance of myxedema is established.

During the past few years I have observed several patients who have exhibited a number of functional symptoms in common. It is my purpose in this brief paper to describe what I believe to be a clinical syndrome. No attempt will be made to expound the deeper philosophical minutiæ which the consideration of any psychopathological condition necessarily implies. The patients that I have in mind all were women, they all were in the 5th decade of life, they all were over weight, their basal metabolic rates were not reduced markedly if at all, the prevailing emotional tone was one of moderately severe depression without delusional formation, and the patients all were normalized by the administration of desiccated thyroid gland. Every patient had consulted numerous physicians, had received varying doses of bromide and other sedatives without relief, had listened to the usual "pep-talks" and other attempts at psychotherapy, all to no avail. Before receiving desiccated thyroid they had been suffering for from several months to several years in a state of chronic anxiety and moderately severe depression. They were given thyroid extract and, without sedation, without psychotherapy and without any supervision whatever of their life activities, they became physically and psychologically normal.

---

*Read before the annual meeting of the Minnesota State Medical Association, Duluth, Minnesota, June 30, 1938.

Case Reports

Because of limitations of time and space, only three illustrative cases will be reported. Numerous other cases have been seen in private and dispensary practice. Only relevant psychiatric data will appear in the case reports.

Case 1.—Mrs. D. L. L., a divorced housewife, aged forty-two, was first seen by me in the Ancker Hospital Dispensary, Saint Paul, on June 18, 1935. Eight years previously she had had an hysterectomy and since that time there had been hot flashes and amenorrhea. In addition she was depressed and disinterested in her surroundings. Although there were no specific preoccupations, Mrs. L. had frequent crying spells, felt worse when she awakened in the morning, entertained thoughts of suicide, and felt extremely hopeless about the future. The physical and neurologic examinations were negative. The serologic tests on the blood and cerebrospinal fluid gave negative results; Hb. 91 per cent; R.B.C. 4,860,000; W.B.C. 8050 with a normal differential distribution; B.M.R. —13 per cent. Examination of the expressed gastric contents after a test meal gave normal values for HCl. The patient's weight was 210 pounds; pulse 76, temperature normal. Mrs. L. was placed on desiccated thyroid and almost at once began to feel better. I saw her at weekly intervals for the first two months, and the thyroid dosage was regulated to produce weight loss and to support the emotional tone without producing toxic symptoms. Mrs. L. now weighs 188 pounds (a loss of 22 pounds), her basal metabolic rate is +9 per cent, and she feels perfectly well. Her maintenance dose is 2 grains of dessicated thyroid daily.

* * *

Case 2.—Mrs. A. J. E., a married housewife, aged forty-two, was first seen by me at Ancker Hospital Dispensary on June 4, 1937. At that time she was suffering from what appeared to me to be a typical involutional depression. She was depressed and disinterested, had daily crying spells, felt worse in the morning, and had a great variety of somatic preoccupations. She was afraid that she was going blind, afraid that she would lose her mind, afraid that she had abdominal cancer, and she tearfully resented any suggestion to the effect that she might be mistaken. From the very first interview she seemed to be on the defensive, and interrogation revealed the fact that she had consulted a number of physicians and had been told that there was nothing wrong with her, that it was "all imagination," and that she should "snap out of it." She had taken large amounts of sedative, all without relief. The physical and neurologic examinations resulted in negative findings throughout. Hb. 82 per cent; W.B.C. 8350 with a normal differential distribution; urinalysis normal; gastric expression not permitted, and the basal metabolic rate not determined because of a technical difficulty in the laboratory at the time. Serologic tests on the blood and cerebrospinal fluid were negative. The weight was 194 pounds, pulse 100, and temperature normal. Mrs. E. was placed on 2 grains of desiccated thyroid daily, and one week later reported that she was feeling better. Two weeks later the weight was 187 pounds, pulse 96, and she reported that she was feeling much better during the day but was unable to sleep at night. One month later her weight was 181 pounds, pulse 96, and the patient reported satisfactory progress. On August 26, 1937, she reported that she was very nervous. Her weight was 178 pounds, pulse 98, and the basal metabolic rate was +34 per cent. Thyroid medication was discontinued and within ten days there was a return of all the mental symptoms. Thyroid extract was again given in smaller doses and carefully supervised. By February 10, 1938, Mrs. E. was free from crying spells, she was doing all of her own housework, her weight was 155 pounds, pulse 88, and basal metabolic rate +15 per cent. I last saw the patient on April 12, 1938, at which time she reported that she thought that she was cured.

* * *

Case 3.—Miss M. G., a clerk, aged forty-nine, consulted me in April, 1935, stating that she had been chronically depressed for six years. Her trouble began following a middle ear infection which she wrongly believed would result in mastoiditis, meningitis and death. At that time her preoccupation with the ear condition amounted almost to a somatic delusion. She was referred to an internist who gave her digitalis and placed her under supervision. A few months later the internist referred her to a neurologist who attempted a modified psychoanalysis. The patient was hospitalized for fourteen weeks and daily interviews were held with her in an effort to explain her fears and phobias on the basis of a sex repression. The woman being a frigid virgin and a very religious person besides, reacted to that form of psychiatric investigation in a very unsatisfactory manner. She became more and more depressed, developed ideas of self-accusation, and was convinced more than ever before that she was kind of a sexual pervert. When I saw her she was very much discouraged. She cried a great deal, had ideas of suicide, was unable to take any interest in her usual activities, slept very poorly at night, and her self depreciation was intense. Her ideas concerning fancied sexual perversion were very vague, poorly defined and unsystematized; but they formed a prominent part of the psychiatric picture. Although she weighed 210 pounds, and complained of easy fatiguability, I did not think of the possibility of hypothyroidism until the fall of 1936. At that time Miss G. began to complain that her hair was falling out, and she had missed two menstrual periods. Her psychiatric status was very much the same as it was at the time I first saw her. A basal metabolic rate determination was made and found to be —16 per cent. The gastric contents did not contain any free HCl; Hb. was 74 per cent; R.B.C. 3,940,000; and urinalysis negative. The patient was given dilute HCl and 2 grains of desiccated thyroid gland daily. She failed to lose weight or to notice improvement in her mental condition until she reached a maintenance dose of 5 grains daily. She is now taking this amount. Her weight is 185 pounds; Hb. 82 per cent; R.B.C. 4,500,000; urine, normal; menses, regular. Mentally she is very well. She occupies a responsible position, and in addition to that is meeting a very distressing home situation very adequately.

Comment

One must admit that in the cases reported above, hypothyroidism was not proven to be the cause of the psychiatric deviation. Ravin[4] states that when we speak of an individual as having myxedema we refer to the entire syndrome—slow mentality, dry skin, non-pitting edema, elevated blood cholesterol, etc., and not to the single feature of myxedematous infiltration of the tissues. He believes that since decrease or absence of thyroid secretion results in a state of myxedema in all of its features, we must consider myxedema as a manifestation of diminished thyroid secretion. Myxedema and hypothyroidism imply more than hypometabolism, and the terms should not be used in the absence of other evidences of diminished thyroid function, says Ravin. On the other hand, Hensel,[1] and Mason et al.[3] agree that it is possible to have true hypothyroidism without myxedema. In fact, Mason believes that the blood cholesterol is a more reliable indicator of hypo- or hyperthyroidism than the basal metabolic rate.

Whether or not the mental symptoms in the above cases were due to hypothyroidism or to hypometabolism from any other cause, increasing the metabolic rate by the feeding of desiccated thyroid did normalize the emotional reactions when other forms of treatment failed. It might be said that increasing the metabolic rate enabled the patients to establish compensation at the psychologic level and thus to meet their life situations in a more efficient manner. Bearing in mind the psychobiologic equation "Individual plus Situation equals Reaction" we might say that in some people the reaction of the individual without thyroid to a life "Situation" is one of mild melancholia. Just as in myxedamatous patients the electrocardiographic voltage is increased by the administration of thyroid gland, there evidently are other individuals whom increase in their "psychic voltage" helps to meet life situations. Without thyroid stimulation these people are inadequate, and they fail to compensate at the psychologic level. Stimulated by the administration of thyroid medication they find themselves able to react normally and adequately, and the resultant emotional tone is one that is not painful or distressing. It must be remembered that these people are not myxedematous and their basal metabolic rates are not reduced to any considerable degree. In this respect the clinical picture just described differs from that of the true myxedematous psychoses, and for this reason its cause is more liable to be overlooked.

Summary

Certain women in the 5th decade of life who are overweight and who have slightly reduced basal metabolic rates suffer from a form of chronic nervous depression which is relieved by the administration of desiccated thyroid.

Discussion

Dr. L. R. Gowan, Duluth: I am sure we are all grateful to Dr. Kamman for presenting this series of cases, pointing out the psychic manifestations that one occasionally sees in a patient presenting glandular imbalance in which the thyroid may be the offending

ITY OF MARYLAND
LI ARY

member. With our increasing insight into the importance of the consideration of each individual patient from a psychosomatic viewpoint, it becomes more and more apparent that psychiatric pictures are frequently due to physiological imbalance, as well as the fact that practically all somatic disease has a psychic component which plays a large part in determining its eventual outcome.

With particular reference to the cases cited, the question arises as to what result might have been obtained if these patients had been treated from the standpoint of pituitary dysfunction primarily, and thyroid secondarily. Dr. Kamman did not state whether any one of these patients had been treated from the standpoint of ovarian dysfunction, although they were all within menopausal age limits.

The average physician confronted by a woman in the forties presenting nervousness, characterized chiefly by depression, usually thinks of the possibilities of glandular imbalance, in which, of course, the thyroid is frequently involved. In the absence of objective signs of organic disease it is not enough to tell the patient that she is "just nervous and to go home and forget about it." Whether the reason is organic or emotional, there *is* a reason for every evidence of emotional disturbance which can be discovered in a very high percentage of cases, if sufficient time and painstaking search is made. When one realizes that at least 40 per cent of all patients have no physical disturbances, but have complaints based on emotional imbalance, it is apparent that the greatest deficiency in American medicine today is the neglect and misunderstanding on the part of the average physician of the importance of emotional balance, not only in preventing signs of nervousness, but also preventing the inception of organic disease and aiding its ultimate cure.

The lessons that we have learned from Dr. Kamman's presentation are so evident that they need no elaboration from me. However, I should feel that I were neglecting a wonderful opportunity if I did not stress to this group the importance of the mental hygiene approach to every patient in all branches of medicine. In doing this, allow me to refer to the work of Dunbar and her collaborators in New York which has been carried on over a period of eight years, under the title of "The Psychic Components of the Disease Process," the first report of which was presented at the annual meeting of the American Psychiatric Association in St. Louis in 1936 and the second report presented on June 7 of this year at the meeting of the American Psychiatric Association at San Francisco. These workers have studied the importance of the Psychic Component of the Disease Process in some 1,400 patients.

With your permission, let me read the conclusions of their first paper:

"1. Much of present-day medical treatment of somatic ailments is purely palliative and symptomatic in the sense that many somatic ailments (as well as many manifestations in the physical sphere which used to be considered organic disease entities) are merely symptoms of an underlying disease process developing in psychic and somatic aspects. This is borne out by our findings in the groups of patients reported.

"2. The psychic component may be determinative in illness, no matter how 'organic' this illness may appear to be, with the qualification that from the point of view of therapy as opposed to palliation, it is more significant in illnesses or phases of illnesses where the pathological changes are still reversible.

"3. From the point of view of the hastening of convalescence and the guarding against relapse, the rôle played by the psychic factor is determinative in a considerable proportion of patients (as reported here for patients with cardiovascular disease, diabetes, and fractures) although its exact nature and extent should be investigated further.

"4. It is probable that the psychic factor is specific, at least for certain disease processes or syndrome, such, for example, as "essential hypertension."

I realize that I have digressed considerably from the discussion of the paper just presented. However, I feel keenly about the need for the psychosomatic understanding of disease and I wished to grasp this opportunity to emphasize it.

Again I thank Dr. Kamman for his presentation.

FRACTURE OF THE ELBOW AND VOLKMANN'S ISCHEMIC CONTRACTURE*

HENRY W. MEYERDING, M.D.

Rochester, Minnesota

THE prevention of the disabling and disfiguring complication, which is seen most commonly among children, following fracture of the elbow, and which is known as "Volkmann-Lesser paralysis," "Volkmann's ischemic paralysis," "Volkmann's myositis" or "Volkmann's contracture," is of interest to every practicing physician. Although it may occur in cases in which the fracture has not been treated by a physician or by any form of fixation, there appears to be a belief that negligence and unskilled management on the part of those who are in charge of the treatment is the cause of this condition. This is the basis on which malpractice suits are founded. Since the time Volkmann first described the condition in 1869, various theories have been advanced as to its etiology and there have been different opinions as to the methods most efficacious in its treatment. I believe that the factors involved in its causation are now understood. The physician who carefully observes, and has the coöperation of his patient, who is cognizant of the early symptoms, and who carries out measures to prevent interference with the circulation of the forearm, may avoid the occurrence of this contracture. The general practitioner sees the majority of these patients first and it is his responsibility to see that the delicate soft tissues are not allowed to become irreparably injured as a result of intrinsic or extrinsic pressure. A record of the findings at the time of the first visit of the patient should be made. This record should include the interval between the injury and examination, as this has often an important bearing on the extent of swelling and cyanosis. The character of the pulse and presence of paralysis may determine the type of treatment. In those cases in which the physician finds serious impairment of circulation, he should request a consultation to protect himself and to give his patient the benefit of possible added skill in meeting the impending complication. The patient's family appreciates the gravity of the situation more than does the patient. The concern of the family, when consultation is obtained, results in a better understanding of the situation and lessens the likelihood of medico-legal entanglements should the result be unfortunate.

---

*From the Section on Orthopedic Surgery, The Mayo Clinic, Rochester, Minnesota.

Abstract of lecture presented March 12, 1938, at the University of Minnesota Chapel, Center for the Continuation Study, Minneapolis, Minnesota.

Prompt and skillful treatment of fractures about the elbow in cases in which there has been no serious injury to blood vessels or nerves usually produces excellent results unless infection as a result of the primary injury or surgical treatment complicates the picture. What are the factors, then, which are present and which produce the ischemic contracture? The common fracture associated with this contracture is of the supracondylar type, in which the force that breaks off the lower fragment of the humerus carries the condyles backward and strips the periosteum away from the posterior surface of the humerus. The space thus formed promptly becomes filled with blood. The lower fragment is carried forward, pierces the periosteum, and may impinge on or cut blood vessels or nerves in its further downward course. The blood which forms about the site of the fracture infiltrates the antecubital spaces, compresses the soft tissues, and if there is a large amount of blood it may pass downward into the forearm. Should there be a ruptured artery, this intrinsic pressure alone may be sufficient to cause serious interference with circulation, which is of such magnitude as to produce an ischemic contracture. In cases in which improper transportation produces repeated movement of the fractured parts, further swelling and hemorrhage result and there is the possibility of laceration of previously impaired nerves, blood vessels and soft tissues. The thin walled veins are the first to become compressed and the return circulation is impaired or is completely cut off. The muscle spasm holds the bones in an overlapped position, which adds to the pressure, and the proximal fragment may impinge on the vessels and cause further injury. If no treatment is carried out, this fracture may result in malunion with, or without impairment of movement, or ischemic contracture. Should arterial hemorrhage continue, the subfascial hematoma produces distention, extreme pain, and tenderness at the antecubital space, and cyanosis, loss of pulse and numbness. The hemorrhage into the forearm is confined by the interosseus membrane, radius, ulna and the inelastic aponeurosis of the flexor muscles. The forearm, hand and fingers become cold, wet, pulseless and cyanotic and blebs appear. Pain is very severe, and unless intrinsic pressure is relieved, contracture occurs. It is a matter of hours, not days or weeks, before muscle tissue is injured, and the patient, as a result of unavoidable circumstances, may not have seen a physician or may not have had any form of treatment whatever. Should the patient arrive in such condition, expecting the fracture to be reduced and his arm put in a splint so that he may return home, an immediate consultation and hospitalization should be demanded, and a record should be made and witnessed for the protection of the physician.

Unfortunately, the general practitioner is forced to travel considerable distances daily and as a result is compelled to depend on others who often are unskilled to carry out his instructions. He may reduce a fractured elbow satisfactorily and leave his patient comfortable and free of pain, only to find on his return that swelling has occurred and serious injury has resulted. In some instances he will find that the fragments have slipped and unless he checks the reduction by roentgenographic examination he will be confronted with malunion. In 40 per cent of a series of cases of Volkmann's ischemic contracture, which was associated with supracondylar fractures, the fractures were malunited. Usually, the distal fragment was found malunited in a posterior position; occasionally, lateral displacement results in loss of carrying angle. The value of anteroposterior and lateral roentgenograms, which are made before and after reduction of the fracture, cannot be overemphasized. Under ideal hospitalization and nursing care, the physician has more protection against undue swelling and its disastrous results than he has otherwise.

Nurses and assistants should be instructed, however, to look for symptoms of impaired circulation.

In cases in which the swelling is sufficient to make reduction difficult and in cases in which immobilization in flexion with splints or casts results in pain, it is advisable to remove constricting dressings, place the patient in the recumbent position and elevate the arm. Should pain and swelling increase sufficiently to cause cyanosis or interference with the circulation, it is advisable to abandon the treatment of the fracture and care for the soft tissues. Of what use is treatment which results in good position of the bony parts at the expense of the function of the extremity? A properly reduced fracture that is held in position by retentive splints should not require opiates for relief of pain. Suspension of the arm above the recumbent body for a few days usually will permit reduction of the fracture after swelling subsides, without risk of incurring excessive pain or ischemic contracture.

When patients are ambulatory, the airplane splint is excellent and aids in the prevention of edema. Why so many patients are permitted to be up and about with arms swollen and cyanotic and hanging at their sides is difficult to understand.

A third group of patients are seen after the antecubital space is distended and tender and the pulse is faint; the skin has then assumed a bluish-red color and pain is unbearable, opiates having often been freely administered. If splints, bandages, adhesive tape, or casts have been applied, they should be removed and the arm should be elevated on pillows, with the elbow extended beyond a right angle. Warm, but not hot, moist dressings should then be applied. If within the next hour the swelling increases and the pulse is absent, the relatives must be warned as to the seriousness of the situation and preparations should be made to operate. Intrinsic pressure has in such cases become sufficient to block the venous flow, but the stronger-walled artery still permits a little blood to be forced into the arm. In the cases of older patients with impaired blood vessels and feeble hearts gangrene is possible, but in children the stage is set for ischemic contracture.

A fourth group of patients is encountered after several manipulations have been performed and considerable time has intervened since the fracture. The arm is then distended to such an extent as to demand immediate relief through surgical measures. There is no time to be lost, as degenerative changes may not be complete and viable tissue may yet be saved. It is at times impossible to judge accurately as to the amount of damage done to the nerves and blood vessels, for the circulation is no longer active and, with its loss, the nerve supply becomes numbed and the finer distinctions of sensation and motion are lost. Relatives should be advised and operation resorted to in the hope of preserving the function of the forearm, treatment of the fracture being of secondary importance. Skeletal traction, by means of a Kirschner wire through the olecranon, is an excellent method of correcting malposition of the fragments and should not in certain cases be overlooked as a useful aid, either as a preliminary to exploration of the hematoma or after careful operative inspection of the brachial artery and median nerve. Free incision over the hematoma and through the deep fascia liberates muscle tissue and blood which have been under tension. An incision mesial to the biceps permits the bicipital fascia to be divided close to the tendon, and the artery, vein, and nerve can readily be inspected. Complete rupture of the brachial artery has been observed as well as partial or complete severance of the nerve. The deep fascia over the forearm may require division, and this may be done subcutaneously by means of a special knife. The fracture may be reduced and internal fixation used by means of bone screws or Kirschner wire which may be passed up through the condyles into the proximal fragment. The entire arm is then enclosed in a large, moist alcohol and boric acid dressing and is suspended in abduction. The physician who has mastered the preventive measures described is in a position to meet the complications following supracondylar fractures in children and to prevent many of the disastrous complications of ischemic contracture.

Conservative Treatment of Volkmann's Ischemic Contracture

Volkmann's ischemic contracture may occur in a few hours, and the earlier treatment is begun the better the results will be. The consultant is often called after the contracture has been present for some time, and he finds the wrist flexed, the metacarpophalangeal joints extended, and the phalanges acutely flexed. Motion at the elbow is often restricted and the hand is held in pronation; supination may be impossible and numbness of the forearm exists. As the damage to the soft tissues may be benefited by release of intrinsic pressure, a consideration of the methods previously described should be given. No time should be lost in attempting gradual extension of the involved muscles, and the stretching method of the late Sir Robert Jones is generally recognized as excellent.

While the wrist is acutely flexed, it will be found that the fingers can be extended. Metallic splints are then fitted to each finger to maintain the corrected position. The patient now attempts systematically to extend the metacarpophalangeal joints, which are contracted. In a few days the joints stretch sufficiently to allow the application of longer splints, which extend to the wrist. After the wrist is exercised for a few days the splint is extended to the elbow, and among such splints can be used those which maintain extension of the hand. Thus the contracture is gradually and painlessly overcome.

I have found many splints in use, but prefer the simple and inexpensive wooden tongue-depressors found in every physician's office. With these padded and held by strips of adhesive tape, the principles of Jones may be carried out until stretching of the wrist requires longer splints, which are usually made of a thin piece of boxwood. The use of rubber bands to pull the extended hand toward the longer splint is useful in extending the wrist. The banjo-splint, used with rubber bands fastened to adhesive on the fingers permits the fingers to be exercised at all times and is most efficient; it is inexpensive, can be made in a few minutes, and permits the patient to be cared for at home.

Care must be taken to gain the confidence of these children, and after a short time they will become interested and will coöperate exceedingly well. Thus the first few treatments may consist of heat and whirlpool baths combined with light massage. The splints soon may be adjusted and worn during the intervals between treatments. Active motion is performed willingly, and as confidence is gained active motion may be supported by gentle passive motion and electrical stimulation. We at the clinic rely principally on heat and massage as aids to gradual stretching and do not believe that painful, passive motion or forceful manipulation under anesthesia is advisable.

The next stage in the treatment of Volkmann's ischemic contracture is that in which several months have elapsed since fracture, during which time treatment has been inadequate. The pain and swelling are gone and the hand is sensitive to cold and has the typical claw-like position; motion is limited. Usually the hand is held in pronation and there is limitation of motion in the elbow. Ulceration and scars from pressure of splints and bandages are not infrequent. Paralysis from primary injury, or secondary to scar formation, may involve one or more of the main nerve trunks. The radial pulse may be absent, and the arm and hand have lost the cyanotic appearance and are white. Attempts to straighten the fingers with the wrist extended brings out the tight flexor tendons and the hard atrophied flexor muscles; the finger nails cut into the hand of the examiner. The extensor group of muscles are, on the other hand, preserved or only slightly involved. There may be atrophy of bone, myositis ossificans, and roentgenograms may disclose malposition of the fracture, requiring correction. All forms of treatment now prove less satisfactory, and prolonged and adequate conservative treatment is best. First the Jones, or banjo-splint, method of extension, combined with physiotherapy, should be tried. When this has failed, the next stage is reached and surgery may now render the contracture more responsive to conservative treatment.

In the third stage a group of deformities of longer duration are encountered, years often having passed with the contracture persisting in spite of treatment. Marked contracture, atrophy of bone, scars, contracted capsules, nerve degeneration and impaired circulation, and a rope-like musculature challenge the most expert surgical care. The surgeon must now realize that no matter what type of operation is performed nor how skillfully it is done, he cannot bring about complete cure; when all other means have failed he is the only recourse, and he plans the operation in the hope of bringing about an improved cosmetic result and some return of function. If the flexor muscles are entirely fibrous the prognosis is poor. The surgeon should also remember that without careful postoperative care and prolonged and intelligent physiotherapy he can accomplish little.

Through lengthening of tendons the surgeon is able to obtain extension of the fingers and wrist, the extent and benefit of this procedure depending on the damage done. A longitudinal incision parallel to the palmaris longus muscle is made and the vagina fascia is divided, exposing the muscle and tendon. By retracting the fascia, the superficial group of muscles are exposed and the tendons lengthened by making two oblique sections, 2.5 cm. apart, three-fourths of the distance across the tendons and stretching them by means of a forceps passed underneath. The usual muscles lengthened are the palmaris longus, flexor carpi radialis, flexor pollicis longus, and flexor digitorum profundus. In some instances the surgeon will find the median nerve bound down in a fibrous scar and neurolysis will be advisable; also, the tendency to supination in the more resistant cases may be benefited by section of the pronator quadratus or the pronator teres.

I have observed a considerable difference in the amount of fibrous scar tissue and fixation of the structures about the wrist. In some cases it is possible to leave the tendons in their sheaths during operation, and a minimum of retraction, and scarring, and adhesions result. When lengthening of the flexor pollicis longus and flexor digitorum profundus is performed, considerable more trauma is likely to result, binding the entire mass in scar tissue. With care this operation may be carried out with distinct satisfaction to the patient; it allows correction of the deformity and improved function.

Neurolysis is beneficial, especially when pressure sores are obvious and scars cause contracture and fixation of the nerve. The findings at operation frequently lead the surgeon to conclude that the entire ischemic contracture is the result of injury to, and fixation and degeneration of, nerves. I feel that the changes in the nerves are usually secondary to the ischemia unless a primary injury or rupture occurs at the time of accident or manipulation. I have seen complete rupture of the median nerve following supracondylar fracture and ischemic contracture. In this series of cases the radial nerve was most commonly injured.

Resection of bone is resorted to in long-standing cases of contracture in which the tendons are extremely short and all attempts at conservative treatment have failed. A bone graft may be used to bridge and maintain the wrist in extension. The stretching of nerves and blood vessels after years of contracture, during which time the bone has grown and the tendons have remained as they were, is impractical. I cannot agree with some who condemn this operative procedure of removal of bone. There is a group of older patients with long-standing deformity in which resection of the carpal bones or radius and ulna gives excellent cosmetic results and a measure of functional benefit.

Lowering of the common origin of the flexors at the epicondyle is an operation which partially releases contracture and is used in combination with gradual stretching. It may be performed at the same time the median and ulnar nerves are examined.

When the proximal end of the humerus projects forward in malunion, preventing flexion of the elbow, or excessive callus formation or an ossifying hematoma exists, excision of the bony mass may be of benefit. Often there is contracture of the capsule of the elbow that will require capsulotomy. The biceps tendon may require lengthening as a result of involvement of the muscle from ischemia or long contracture. Even arthroplasty of the elbow would be preferable should the foregoing measures fail to permit movement and the function of the arm be not too seriously damaged. Sympathectomy has not as yet had a fair trial, but in one case it seemed to be of some aid.

Several patients have been encountered who had such extensive and long-standing deformity and disability as to warrant amputation, in order to rid them of a useless and unsightly deformity.

The prognosis depends on many factors: the age of the patient, the type of bandages, splints, and casts used and whether they have caused pressure sores and scars, the extent of hemorrhage, and whether good union or malunion was obtained, whether infection was present or there was damage to blood vessels or nerves, the presence of an ossifying hematoma, and degree of contracture and extent of fibrosis of muscle.

PRACTICAL POINTS IN ANESTHESIA*

RALPH T. KNIGHT, B.A., M.D., F.A.C.S.
Associate Professor of Surgery and Director of Division of Anesthesia
University of Minnesota, Minneapolis, Minnesota

THE subject for this paper was selected by the program committee and accepted by the writer. It does not attempt to present anything new or striking but rather to emphasize certain useful facts and procedures which are helpful in obtaining good sedation, pain relief, and operative facility with safety.

About twelve years ago a man came into my office, said he was a morphine addict and very much needed some morphine relief. I called the federal narcotic office, checked his identity, and obtained permission to administer some morphine. When I had prepared it the man said, "May I please give it myself?" He threw his handerchief around his arm, held it with his teeth, tightened his fist, adroitly inserted the needle into a vein in his forearm and sighed with relief as he pressed the piston home. When I told this to a doctor friend, he said he had had the same experience some time before and since then had always given morphine intravenously for relief of acute pain. I too have always done so since and so have many others. If the drug is dissolved in at least 2 c.c. and injected slowly, the pain will be relieved as soon as an adequate amount has been injected whether that amount is 1/12 grain or ½ grain. One is protected against giving an overdose or giving an inadequate dose and waiting fifteen to thirty minutes to know whether relief is to be obtained. The patient has the benefit of immediate relief. Morphine preparatory to a painful examination, manipulation or dressing, or before an emergency general anesthetic, may also often be best given intravenously. Sometimes when local anesthesia has been selected as the anesthesia of choice but the patient has had insufficient sedation, is afraid, excited, and unduly sensitive to the discomfort of the needle, this method of giving morphine is the best possible treatment. In all these latter circumstances, without the relief of pain to guide the dose, the injection must be made slowly and stopped as soon as any of the following symptoms appear: dizziness, weakness, sleepiness; or tingling, numbness, or aching in any part of the body. If the injection is made too rapidly, twitching or even convulsions may ensue. As soon as the proper dose has been given, the patient is at ease mentally and physically and unconcerned about the painful examination, dressing, manipulation, or injection of local anesthetic.

If real anesthesia is needed for some still more painful but presumably short procedure, one of the short acting barbiturates is available for intravenous use and represents one of the greatest advances in anesthesia. Evipal and pentothal sodium should be used in 5 per cent solution. About 1 c.c. should be injected each 10 seconds until the patient is unconscious and then 0.5 to 1 c.c. intermittently as required to maintain the desired level of anesthesia.

Support of the jaw and maintenance of an open airway is absolutely essential. Lundy's "butterfly," a wisp of cotton or slip of tissue attached by adhesive before the nostrils and lips, is a simple and helpful device and should always be used. The respiration tends to be so quiet and shallow that it is otherwise difficult to be sure that it is not being obstructed. Adequate relaxation for reduction of a fracture may be obtained immediately, but continuance of good relaxation, for any purpose, is unsafe because of the danger of respiratory-center paralysis. High concentration of the drug in all body tissues is produced, and recovery from a slight excess is no longer prompt.

One should never be tempted to use the intravenous barbiturates for procedures within the mouth and pharynx or even in the nose and antra. Muscles of the jaws and of the throat are not well relaxed by these agents without closely approaching paralysis of the respiratory center, and spasms of jaw, tongue, pharynx, and larynx are easily set up by any attempted manipulation, causing respiratory obstruction which is often well-nigh impossible to correct. A very difficult and dangerous situation develops in a high percentage of attempts to do such work under such anesthesia. If obstruction occurs, respiratory effort almost immediately ceases.

---

*Read before the annual meeting of the Minnesota State Medical Association, Duluth, Minnesota, June 30, 1938.

Although the patient will awaken in a few minutes after the injection is discontinued at the end of a normal anesthesia, it must be remembered that coördination and judgment may not return to normal for perhaps an hour or sometimes two or three hours, especially if the anesthesia has been at all prolonged. If the patient must leave, he must leave as a patient, with a competent person to take care of him.

In the field of local anesthesia several special points are worth bringing up in such a discussion as this. One of the commonest uses of local anesthesia in office practice is for the removal of sebaceous cysts. The injection method of Dr. F. Z. Havens of Rochester is the simplest and most practical. The point of the fine small wheal needle is inserted into the skin over the center of the cyst. An intradermal wheal of 1 per cent procaine is started which is of course just outside of the sac of the cyst. Without changing the position of the needle at all the injection is continued until five, ten, or even fifteen c.c. have been injected. The wheal spreads out and the fluid spreads around the sac in all directions, dissecting it from the outer layers of the skin. The anesthetic solution follows the line of cleavage and tends to dissect out the entire sac, even though it may be a large one, so that when a shallow incision is made down to the surface of the sac, it delivers itself with almost no additional aid. If the cyst has been inflamed and has become adherent, it may be necessary to take out some surrounding fat in addition to the sac. It is then best to do a field block, surrounding the cyst with a linear subcutaneous injection introduced through two opposite skin wheals and then through one of these wheals a needle is inserted underneath the cyst and it is "teed up" by a deposit of 10 c.c. or more. The field is anesthetized in this same latter way for the removal of a lipoma. This method is much more satisfactory than injecting the line of incision and then indiscriminately infiltrating all tissues before entering them. The same is true of anesthetizing the abdominal wall. The lower intercostal nerves run diagonally forward and downward between the transversalis and internal oblique muscles to the rectus sheath, which they enter, and then divide to supply the peritoneum, the muscle, and the skin. If the incision is to be made through the mid-line, or one of the recti muscles, a row of wheals about 2.5 or 3 inches apart is placed from the xyphoid to the outer margin of the rectus, thence downward along the rectus margin. Through each wheal a needle is inserted into the rectus sheath and 10 c.c. of 0.5 per cent procaine is deposited in each place. All of these pools flow together, thus surrounding all the nerves as they enter the sheath. Skin, muscle, and peritoneum are anesthetized and the incision is made through normal, not edematous, tissues. When an anesthetic solution is injected, with the needle remaining in one postion, aspiration must be done frequently to make sure the solution is not being injected into a vessel.

A present day development is the production of anesthesia by the injection of the solution peridurally in the vertebral canal, between the ligamentum flavum and the dura, at any desired vertebral level. Twenty-five to 50 c.c. of 2 percent procaine are injected, which surrounds the nerve roots as they emerge from the dural sac, and a zone of anesthesia about eight vertebral segments wide is produced. Most of the hazards associated with spinal anesthesia are avoided and the duration is usually longer. It will behoove us to follow the development of this procedure.

Regarding spinal anesthesia, there are some points which can not be too often stressed. It has long been generally recognized that it is unwise to administer spinal anesthesia to a patient whose central nervous system has been subjected to injury or disease such as trauma, new growth, syphilis, poliomyelitis, pernicious anemia, etc. Subnormal neurons are more apt to be unduly or even permanently affected by the anesthetic, or, if they are not, the anesthetic may have to bear the onus of further development of the disease. It is unfortunately not so generally recognized that the nervous tissue is made more vulnerable by any state of depletion of the general health. Undernourishment, loss of weight, anemia, toxemia, and even lack of activity from confinement to the house or bed,—all of these increase the susceptibility to spinal anesthetics as well as general anesthetics. In the presence of these condtions one must decrease the dose and increase the dilution of the spinal anesthetic. Lundy has well demonstrated that 6 per cent, or 7 per cent at the very most, as the solution leaves the syringe, is the highest concentration which can safely be used, and often it is best to reduce the concentration to 2.5 or 3 per cent.

There is too general a feeling that spinal anesthesia has been a failure, and should not have been used, if it is necessary to supplement it with general anesthesia. I believe this is a wrong conception. Unless general anesthesia is absolutely contraindicated, the only disgrace connected with adding it to spinal anesthesia is in not adding it soon enough. It should be started at the very first indication that the spinal anesthesia is beginning to wane. Then it will be possible to do with a minimum of the general anesthetic. A delay of five minutes will probably double the amount of general anesthetic necessary. One should of course know how to produce as long a spinal anesthesia as may be safely obtained, but in many cases the patient will be best served by administering a very conservative dose of spinal anesthetic and then immediately superimposing unconsciousness by a minimum dose of general anesthetic. The relaxing effectiveness of the small spinal dose will be greatly increased and prolonged and the patient will not be harmed and will likely be the happier for the respite from consciousness.

General inhalation anesthesia in its present stage of development offers a fascinating field. There is available a variety of gases having various characteristics for varying needs. Fluidity of the gases may be increased by admixture of helium for cases of asthma or other partial obstruction of the tracheo-bronchial tree. Oxygen may be used in varying proportions. Carbon dioxide may be entirely or partially removed, allowed to accumulate or even added, as conditions indicate. Helpful airway devices of the nasal, oral, pharyngeal, intratracheal and even intrabronchial types are available and should be used whenever indicated. It seems to me that in connection with every hospital there might well be a physician who has prepared himself to offer as high a type of anesthesia service as possible. This would be a special boon to hospitals not requiring a sufficient number of anesthesias to warrant the employment of a full-time well-trained nurse anesthetist. If anesthesia is to be only a part-time activity, it certainly can be best done by a physician. I do not mean a physician who regards it as a makeshift, or as an undesired stepchild, or as a personal right, regardless of his lack of skill, simply because he has brought the patient in. I mean one of the community's physicians who is keen in other things, who sees in anesthesia an opportunity for expression of a high type of medical skill, and who will take as much interest and pride in bringing to the community's surgical patients the best obtainable in anesthesia as he does in the diagnosis and treatment of disease in general.

Discussion

Dr. Edward B. Tuohy, Rochester: Morphine given intravenously has a definite place in the field of anesthesia as an auxiliary drug to produce a sedative effect or relieve pain. Its intravenous use also permits the patient to retain full consciousness and thus to cooperate with the operator.

Recently I have acquired, from one of the commercial drug firms, a preparation of morphine sulfate (¼ grain, 0.016 gm.) in 1 c.c. ampules. To increase the ease with which morphine may be administered was the incentive for preparing morphine in ampules. It is my impression from a limited number of cases that the strength of the morphine sulfate prepared in ampules is definitely greater than that prepared by the usual method from tablets. I have found that, whereas $\frac{1}{12}$ grain (0.005 gm.) of morphine sulfate was the usual or average amount necessary to produce subjective effects when the solution was prepared from tablets of 1/6 grain (0.01 gm.), definite subjective symptoms, such as sense of warmth over the body, itching of the nose, and so forth, now are obtained from as little as 1/64 grain (0.001 gm.) when the ampule preparation is used. One can dilute the contents of a 1 c.c. ampule containing ¼ grain (0.016 gm.) of morphine sulfate with 2 to 3 c.c. of distilled water and thus administer a small dose with accuracy and safety.

The intravenous use of morphine for bronchoscopy has proved to be helpful and serves to reduce the nervous tension which many of the patients exhibit prior to bronchoscopic examination. The disadvantage of using the barbiturates for analgesia by the intravenous method for this procedure is that in some cases sufficient relaxation of the jaws is not obtained and the introduction of the bronchoscope is difficult. It is unwise to attempt to increase the depth of anesthesia by injecting intravenously more of a barbiturate, such as pentothal sodium, in such a case, because of the danger of depressing the respiratory center. In most instances, furthermore, the pharyngeal reflexes are somewhat exaggerated during intravenous anesthesia. In selected cases when intravenous anesthesia seems to be indicated for bronchoscopy, it is recommended that the throat be anesthetized by topical applications of 10 to 20 per cent solution of cocaine on cotton pledgets, and that sufficient depth of anesthesia be induced by intravenous injection of pentothal sodium so that the patient does not respond to definite sensory stimuli, such as pinching of the skin. At this depth of anesthesia the jaws should be relaxed reasonably and the bronchoscope can be introduced satisfactorily. The previous anesthetization of the throat by means of cocaine will serve to reduce the activity of the pharyngeal reflexes.

In this connection it may be of interest to mention the use of avertin fluid (tribromethanol and amylene hydrate) for bronchoscopy and for diagnostic ventriculography and encephalography of children. The basal metabolic rate of children usually is between

+20 and +40 per cent, and for the most part, children less than ten years of age tolerate well, larger doses of avertin fluid per kilogram of body weight than adults. The explanation of this phenomenon is that the increased metabolism of children serves to break down and destroy the avertin fluid faster than the lower basal metabolic rate of adults. Therefore, for bronchoscopy and encephalography in children, one can administer between 90 and 100 mg. of avertin fluid per kilogram of body weight. In the presence of pulmonary disease of children, such as pulmonary abscess or bronchiectasis, the use of avertin fluid as an anesthetic for bronchoscopic examination is fairly satisfactory. The relaxation afforded by avertin fluid is more than that produced by the intravenous administration of barbiturates and I believe that it is a safer anesthetic than pentothal sodium to administer to children. This barbiturate administered intravenously to children seems to depress the respiratory center too severely and for this reason it is not recommended except in unusual cases.

The production of adequate surgical relaxation of the upper part of the abdomen by means of spinal anesthesia is a problem which presents many angles. The fall in systolic blood pressure and the nausea attendant on high spinal anesthesia are the two annoying and disagreeable features of this procedure. In relatively tall patients satisfactory anesthesia of the upper part of the abdomen may be sustained by utilizing as sites of injection the upper lumbar interspaces and if necessary, the space between the twelfth dorsal and the first lumbar vertebræ. By using these higher interspaces in other cases one may obtain anesthesia of this region without materially increasing the dose of the anesthetic. When metycaine or procaine is employed for spinal anesthesia for operations on the upper part of the abdomen, the interspace between the first and second lumbar vertebræ usually is used. The dose of the anesthetic will depend on the weight, height, the concentration of hemoglobin, blood pressure and general physical status of the patient. Ordinarily, for upper abdominal operations at least 3.5 to 4 c.c. of cerebrospinal fluid should be aspirated into the syringe which contains the solution of the anesthetic before reinjecting the combined contents into the subarachnoid space. Frequently when satisfactory anesthesia has been obtained for opening the abdomen, the manual manipulation of the tissues about the stomach and gallbladder is disturbing to the patient and surgeon and not infrequently induces nausea and subsequently vomiting. In other cases nausea and vomiting ensue shortly after completion of the injection into the subarachnoid space and considerable muscular straining and motion of the abdominal wall are present.

Often the judicious administration of oxygen and carbon dioxide in cases of slight nausea will serve to control the symptoms, and those patients who are upset emotionally in addition to the nausea may be given a little nitrous oxide and oxygen or cyclopropane and oxygen in order to produce mild analgesia or very light general anesthesia. If spinal anesthesia does not seem to be satisfactory, it is unwise to force deep surgical inhalation anesthesia immediately, because within fiftten to twenty minutes after the anesthetic has been given, the most profound effect from the spinal anesthesia is usually obtained, and if deep inhalation anesthesia is superimposed on top of spinal anesthesia, it is a tremendous load for the patient's vasomotor and respiratory systems to withstand. It is infinitely safer to induce general anesthesia gradually in order to augment the spinal anesthesia and to bear in mind that approximately twenty minutes after the spinal anesthetic has been given the patient's blood pressure, pulse rate and character of respiration should be watched very carefully. In the majority of cases spinal anesthesia for operations in the middle portion of the abdomen, the pelvis and extremities is uncomplicated and ordinarily satisfactory. Because the quality of spinal anesthesia for operations in the upper part of the abdomen is not always consistently good, one may very well consider use of the intratracheal method of general anesthesia in certain cases, especially for patients who are not considered good candidates for local anesthesia. The merits of this method hardly need further amplifications at this time. The method is mentioned because it is such a useful procedure for different surgical operations in the upper part of the abdomen and on the colon.

Probably two of the biggest advances in anesthesia in the last fifteen years have been the introduction of the intratracheal tube as an adjunct to inhalation anesthesia, and the introduction of the short-acting barbiturates as a means of producing intravenous anesthesia. Pentothal sodium and evipal soluble are the two currently favorite agents for intravenous anesthesia and both are substituted derivatives of barbituric acid. The keynote in their use depends on the slow and intermittent or fractional administration. The degree of surgical relaxation is not the same as that afforded by other methods of anesthesia, but there are many indications for their use, especially for operative procedures which do not require more than thirty minutes. In the last year there have been reports by persons, experienced in the administration of pentothal sodium, on use of this type of anesthesia for various abdominal operations. For patients who are not robust or muscular, pentothal sodium may be used for abdominal operations, but its use should be specially indicated.

The indications and contra-indications have been mentioned previously but it is wise to emphasize the contra-indications again, namely, that children less than twelve years of age usually are not suitable candidates, and that dyspnea of cardiac or pulmonary origin in any case is a warning not to use pentothal sodium intravenously. Its use is contra-indicated also for persons who have taken food recently and have a full stomach.

HISTORY OF MEDICINE IN MINNESOTA

HISTORY OF MEDICINE IN RAMSEY COUNTY

BY J. M. ARMSTRONG, M.D.

(Continued from January issue)

In 1857, a census was taken in order to determine the Congressional districts preparatory to the admission of Minnesota as a state. The census was begun in September and finished about the end of the year. The list of those claiming to be physicians, dentists, and druggists, together with the age and place of birth of each, is given here. It differs somewhat from the list in the city directory of 1857-58.

Saint Paul

A. G. Brisbine	32	Ohio	Physician
J. B. Clemens	30	Va.	Physician
J. H. Stewart	29	N. Y.	Physician
L. H. Gabbard	28	France	Physician
J. M. Smith	30	Iowa	Physician
M. D. Patterson	28	N. Y.	Dentist
Thos. J. Vaiden	45	Va.	Physician
T. R. Potts	47	Penn.	Physician
C. Miller	34	Vermont	Physician
D. W. Hand	23	N. J.	Physician
J. W. Wharton	25	Penn.	Physician
Libby Dolbur	35	N. Y.	Physician
Samuel Willey	28	Mass.	Physician
T. D. Simonton	27	Pa.	Dentist
J. H. Studifred	25	N. Y.	Physician
D. C. Price	29	N. Y.	Dentist
A. Berthier	34	France	Physician
H. Welsted	37	Prussia	Physician
Geo. M. Kellogg	28	N. Y.	Physician
J. N. Schroeder	30	Prussia	Physician
S. Knapp	58	Maine	Physician
John Dewey	35	N. Y.	Physician
J. R. Jenks	29	Penn.	Druggist
J. T. Hayward	35	Delaware	Physician
George H. Sperry	50	N. Y.	Physician
L. C. Kinney	43	Ky.	Physician
Wm. H. Morton	28	N. Y.	Physician
John Steele	48	Pa.	Physician
W. H. Eldridge	40	Alabama	Physician
W. H. Wolff	26	Pa.	Druggist
Geo. Hadfield	43	England	Physician
Chas. P. Carver	53	N. Y.	Physician
F. R. Smith	47	Pa.	Physician
D. S. Hutchinson	30	Pa.	Physician
Francis Rieger	30	Prussia	Physician
Thomas E. Master	33	Md.	Physician
A. Berthier	31	France	Physician

County

R. Post	57	Connecticut	Physician
A. E. Boyd	40	Maine	Physician

There are names here that appear in no other place, and considering the circumstances of the census perhaps no opportunity was neglected to inscribe every possible name that might be included. It will be noted that A. Berthier is included twice, J. W. Wharton should be A. Wharton, J. H. Studifred should be J. H. Studdiford, Welstad should be Wedelstaedt, S. Knapp should be C. Knapp, C. Miller should be E. Miller, and Thomas E. Master should be Thomas E. Massey. Schroeder, though listed as a physician, was a druggist and opened a drug store in St. Paul in 1858. As to Clemens, Gabbard, Dolbur, Eldridge, and Carver, no other information is available. Perhaps they were drug clerks. Morton's birthplace was North Carolina, and Berthier probably was born in Berthier, Canada. The directory also lists one James Craig, student of medicine, resident at St. Joseph's Hospital.

Several physicians escaped the notice of the census enumerator, for David Day, J. V. Wren, J. A. Vervais, W. H. Miller, Sawyer, Rosenk, and others already mentioned were undoubetedly in St. Paul at that time. J. T. Hayward came from Wilmington, Delaware. He never practiced medicine in Minnesota, but was interested in real estate. He built a number of business blocks and died in St. Paul in 1859.

1858

No new physicians seem to have come to St. Paul during this year. The panic of the year before perhaps made St. Paul unattractive as a place to locate. Dr. J. H. Stewart, who had been county physician in 1857, sought the position a second time, but a vote by the Board of County Commissioners on January 6 resulted in the election of Dr. Vervais. The position carried a salary of $800 a year, paid quarterly.

1859

The medical happenings of 1859 are as meager as those of 1858. Two new physicians arrived: Wm. Caine, M.D., a homeopath, who inserted his card in the *Pioneer* on January 4, and Dr. Lloyd Dorsey, whose notice appeared on May 11. Nothing further seems to be known about the latter. A Lloyd Dorsey graduated from the University of Maryland in 1821, and a Lloyd Dorsey, Jr., in 1854. He may have been one of these two men. Caine remained here till his death, June 19, 1867.

At a meeting held in August, the trustees of St. Joseph's Hospital decided that "the interests of the hospital would be served by a temporary removal from the hospital buildings to those now occupied by the Academy of the Sisters of St. Joseph." The hospital was too large, for only three or four patients had been received since it opened. Furthermore, the city and county had made other arrangements for city patients. For these reasons the two log buildings on Bench Street, one of which had been the original Chapel of Saint Paul, were again used as a hospital. The arrangements that were made for city and county patients are not definitely known, but since the county commissioners had purchased in February, 1857, sixty acres of land at Pig's Eye (in Sec. 11, T. 28, R. 22, Washington) for a county farm, it may be presumed that the patients were cared for there.

Two physicians died in Saint Paul during the year, Dr. Hayward on May 14, and Dr. C. W. Borup on July 7. In July, Dr. Jno. C. Merrill associated with himself a Dr. W. M. Dunham. Dunham was a nephew of Doctor Boyd; both he and Merrill were homeopaths. Dr. W. E. Braun's name first appears as a resident of Saint Paul in 1859 when he was elected corresponding secretary of the French Canadian Benevolent and Library Association. He remained there several years, then removed to Little Falls. Dr. A. G. Brisbine was appointed a colonel in the State Citizens Soldiery. The exact nature of this office is not known; possibly, the doctor was a member of the Governor's staff.

It might be well, here, to pause in the narrative and review the years previous to 1860, as those years constitute the pioneer years of our history. Sixty physicians of all kinds are reported as having practiced in Saint Paul before the Civil War. Some drifted into other pursuits, but many left for other places as the country opened up and new towns came into being.

The medical problems these men had to face are described in several articles published in the medical periodicals of the day. Those of Wm. W. Finch, and Thomas S. Williamson have already been mentioned. Others include a short note by Dr. J. H. Murphy on Collodion in Mammary Inflammation and Smallpox" (*North Western Medical and Surgical Journal,* Chicago, March, 1851), and the report of Surgeon Geo. F. Turner, of Fort Snelling, in the *New York Journal of Medicine and the Collateral Sciences* for July, 1848 (Vol. 1, New Series, page 21), entitled "An Account of a Severe Form of an Epidemic Miliary Fever which Appeared at Fort Snelling, Upper Mississippi, in the Winter of 1847-48." The disease, no doubt, was scarlet fever. Two paragraphs may be quoted:

> ". . . of the forty-two cases which have come under my care, thirty-seven have been children under twelve years old (and this number embraces nearly all the children in this immediate vicinity), four were adult females and one male. Six deaths have occurred thus far. . . . It has prevailed epidemically among the Sioux Indians of this vicinity while on their winter hunt, attacking indiscriminately all ages and sexes; but with them, from causes probably connected with their mode of life, it has been comparatively mild. In the memory of the oldest Indians, this epidemic has occurred amongst them twice before, and is peculiar to the cold months in this climate."

Dr. Samuel Willey contributed to the *Cincinnati Lancet and Observer* for April, 1856, a well written clinical observation on a case of gangrene of the right lung.

There is also a paper by the Rev. Samuel W. Pond, an early missionary, to be found in Volume XII of Collections of the Minnesota Historical Society entitled, "The Dakotas or Sioux in Minnesota as they were in 1834," giving considerable information as to the diseases of the Indians. He states that insanity and idiocy were rare. A very valuable paper by Dr. David Day dated Winnebago Agency, July 5, 1852, on the diseases of the Indians (Report of the Surgeon General, U. S. Army, in Senate Documents, 1st session 34th Congress, Vol. 18, 1855-56) and other reports from medical officers stationed in Minnesota, may, of course, be found in the Surgeon General's Reports.

A survey of the articles by Finch, Williamson, and Pond reveals that the diseases prevalent in Minnesota at this period differed but little from those prevalent today, except that typhoid fever and intestinal affections have almost disappeared due to the construction of sewers, an uncontaminated water supply, and improvement in the feeding of infants. Cholera, of course has disappeared. Pneumonia was perhaps much more common then, due to the discomforts of the inadequate housing and heating of those days. Most of the old settlers kept warm by wearing buckskin underwear. Scurvy has practically disappeared and probably never will appear again. Perhaps many of the cases denominated scurvy in those days we should now call pellagra. In the early days, when navigation closed on the river there was practically no communication with the outer world as far as the securing of provisions was concerned. In the early fifties, a stage line ran to Galena, where there was a rail connection with Chicago, but little freight could be moved in this way. The late Mrs. Robert P. Lewis stated that she received from her father a present of a gold dollar for Christmas, 1849, and was told that she could buy for herself anything she wished with it. After much deliberation she purchased two eggs to eat on New Year's. The late Mrs. T. C. Schell said that in the winter of 1852 she had a severe cold and expressed the desire for a hot lemonade. Her husband (she was then Mrs. Charles H. Oakes) scoured the town and finally succeeded in purchasing the last lemon in the place, for which he paid fifty cents. Fresh food was so scarce and whiskey so cheap that it is no wonder that deficiency diseases as well as gastric disorders were much in evidence. Protein diet consisted largely of salt pork, although game was abundant, and venison and bear meat offered some variety during the winter. Williamson mentions typhomalaria, a term used indiscriminately in those days, and even much later, for many types of fever and intestinal febrile disorders. It is doubtful if the true malaria was endemic in Saint Paul. No doubt cases were imported by way of the river boats from the south, and during some years it was quite prevalent along the river. Cholera, of course, was imported in this way. Smallpox and measles were common enough. Tuberculosis was comparatively common, inasmuch as many people came to Minnesota to enjoy the advantages of the climate as a cure for that affection. Perhaps it was no more common than in other parts of the country at that time. In the early days our population was made up of the young, the sturdy, and the adventurous, and in the later years of the period housing conditions were better and compared favorably with housing conditions in other parts of the country. Though considered good at that time, living under the same conditions would be considered decidedly unbearable today.

Daniel Drake, in his great work "The Principal Diseases of the Interior Valleys of North America" (1854), says nothing about malaria here, and Ramsey in his inaugural address to the legislature in 1858 denies its existence in Minnesota. As to the treatment of disease employed by our early physicians, one cannot go into great detail. The best of these men were well qualified and compared favorably in the quality of their work with those elsewhere. There are in the Ramsey County Medical Library many books bearing the autographs of our pioneer physicians. Among those published before 1860, which were used for reference, the following may be listed:

Surgery—Dorsey, Gibson, Smith, Druitt, Pancoast, Bell, Cooper, and Miller.
Obstetrics—Dewees, Meigs, Hodge.
Therapeutics—Chapman, Eberle.
Gynecology—Dewees, Eberle.
Pediatrics—Dewees.
Medicine—Thomas, Chapman, Good.
Chemistry—Webster, Henry, Hare.
Anatomy—Horner, Wistar, Bell, Smith, Horner's Atlas.

Other books, Beaumont, Rush's works, some of Holmes' essays, Buchan's "Domestic Medicine," some works on insanity belonging to Willey, and several on venereal disease and dermatology are deserving of mention.

It will be noted that most of these books are by Pennsylvanians. There are several reasons for this, as most of our early physicians came from Pennsylvania or from the West where the Pennsylvania influence was dominant. This applies particularly to Saint Paul. No doubt the fact that Governor Ramsey was a Pennsylvanian attracted many from his former home. Those who came from New York or New England left no books which have come to us. The

American Journal of the Medical Sciences, the *Chicago Medical Examiner,* the *Ohio Medical and Surgical Journal,* the *Boston Medical and Surgical Journal,* the *Transactions of the American Medical Association,* various Cincinnati journals and the *Buffalo Medical Journal* were periodicals read by Saint Paul practitioners.

A perusal of the works to be found in any medical reference library will reveal the medicine of the period. One does not have to be told that there were no synthetic drugs. Calomel, iodides, iron, arsenic, antimony, and lead were the principal minerals used, though large doses of the last three were being discarded. Opium, quinine, digitalis, squills, ergot, and the balsams were the leaders among the vegetable drugs, and a host of other tinctures, extracts, decoctions, and tonics, of much vaunted excellence, were popular, but are now rarely used. The most unfortunate fact of the medicine of this and previous periods was that there was but one drug for the relief of pain—opium. Even if we had but this one drug now, surgery has so advanced that its use would be much more limited. Habitual use of opium and morphine was more common then, both among the people and among some of our early physicians. Also the drug could be purchased by anyone without restriction. Some irregular practitioners gathered vegetable drugs from the woods and fields, but for the most part medical men relied upon prescriptions mixed by pharmacists.

It is believed that the name of every physician practicing in Saint Paul up to this date has been given, and that something is known about most of them. Certainly those of whom little or nothing is known occupied no conspicuous or even mediocre place in the history of medicine in Ramsey County.

1860

In the manuscript division of the Minnesota Historical Society is a photostat copy of the federal census of 1860. This gives name, age, sex, social status, occupation, amount of real estate and personal property, and nativity. The names of persons in the medical profession are given below.

Saint Paul

Name	Age		Born
C. Knapp	60	Surgeon	Mass.
John Steel	50	Physician	Penn.
John J. Dewey	38	Physician	N. Y.
H. Wedelstadt	40	Physician	Lithunia
Alfred Berthier	37	Physician	France
Wm. H. Morton	32	Physician	S. C.
Joseph E. Tertl	28	Physician	Canada
H. N. Bushnell	31	Physician	N. Y.
E. Braun	39	Physician	Canada
Francis Hoffman	28	Physician	France
Wm. Caine	38	Physician	Isle of Man
Thos. R. Potts	50	Physician	Penn.
Gustav Rosenk	42	Physician	Prussia
Francis Rieger	29	Physician	Prussia
Franklin R. Smith	57	Physician	Penn.
Wm. H. Miller	56	Physician	Hanover
F. W. Fusshoetter	28	Physician	Prussia
Sam. Willey	32	Physician	Mass.
D. W. Hand	26	Physician	N. J.
Wm. H. Schell	37	Physician	England
G. A. Vervais	35	Physician	Canada
J. H. Steward	30	Physician	N. Y.
Alfred Wharton	26	Physician	Penn.
A. G. Brisbine	37	Physician	Ohio
Rudolph Albertez	35	Physician	Prussia

New Canada Township

R. Post	60	Physician	Conn.
Edward Boyd	38	Physician	Maine

It will be noted that the list numbers twenty-seven. The omission of Dr. David Day's name cannot be explained. St. Anthony, though still part of Ramsey County, has not been included in the list. Steel should be Steele; Schell's name was Thomas Chatterton Schell. He came here in 1859. G. A. Vervais should be J. A. Vervais, and Albertez should be Alberti. Fusshoetter should be Hostetter. Drs. Mann and Phillips were then living on their farms at Cottage Grove. It will be noted also that the average age of the group is less than thirty-five years. Four of the group were homeopaths (Bushnell, Caine, Schell, and Boyd); and four were irregular practitioners (Rosenk, Miller, Alberti, and Post). No information as to the standing of Knapp, Berthier, Tertl, Hoffman, and Hostetter, is at hand. From other sources it seems probable that the name Tertl should be Hyrtl and that Berthier was a French Canadian, though he claimed to have been born and educated in France. Lithunia should be Lithuania. According to a personal communication believed to be reliable, Hostetter had a saloon on Seventh and Broadway and was the originator of Hostetter's Bitters. He went back to Philadelphia and made a fortune out of his bitters. The late Frank Werner, long connected with the police department, used to help Hostetter make them. Cyrus Knapp apparently was a legitimate practitioner but nothing is known about him. The census showed the population of the city to be 10,279; the entire county contained 12,150 persons. Of the inhabitants of Saint Paul, almost one-half were of foreign birth (4,659). This well illustrates the immigration to our state and city. Of the twenty-seven physicians listed, almost half of them were foreign born. As to the financial standing of these men, J. H. Stewart, whose name is also spelled wrong, was listed as the best off in worldly goods, his property being valued at $40,000. It is a noteworthy fact that in Saint Paul there was one physician of every kind to about every 400 people. Among the foreign names the French still predominated, though Germans were on the increase.

The year 1860 brought no great change in the personnel of the medical profession in Saint Paul as may be seen by the census. Late in the year two more physicians arrived who essayed the practice of medicine in Saint Paul—Dr. D. McCrae from St. Louis, and a Dr. Caldwell who advertised himself as an eye and ear specialist. The cards of these men in the papers are modest announcements, and they were probably legitimate practitioners. The year marks the beginning of local medical societies in Saint Paul. An institution called the Free Hospital for the Poor was established on the corner of Eighth and Jackson Streets in February under the auspices of the ladies of St. Paul's Episcopal Church, then under the leadership of Dr. Patterson. It was hardly a hospital at that time but rather a home for the aged and infirm which served free meals to the indigent and to poor children. More will be said of it later. It is true that a similar institution was started earlier, but there is some confusion as to the relations of the two institutions. The Saint Paul Academy of Medicine and Surgery was formed this year, being, as stated above, the first local medical society. The *Pioneer Press* of April 15, 1860, published a letter to the city council signed by Drs. T. R. Potts, W. H. Morton, and A. G. Brisbine, asking that body to elect Dr. Thomas R. Potts, President of the Saint Paul Academy of Medicine and Surgery, to the position of city physician and health officer.

1861

During the years of the war medical men in Ramsey County took an active part in military affairs. On April 29, Dr. J. H. Stewart and Dr. C. W. LeBoutellier, of St. Anthony, were appointed, by the Governor, surgeon and assistant surgeon respectively to the First Regiment, and on June 15, Dr. T. R. Potts, Dr. J. H. Murphy, of St. Anthony, and Dr. D. C. Patterson, of Winona, were appointed to serve on a state board to examine into the fitness of candidates for appointment to medical positions in the army. Drs. Stewart and LeBoutellier were taken prisoners at Bull Run, and Dr. D. W. Hand was appointed July 25 to take LeBoutellier's place, as it was falsely reported that LeBoutellier had been killed. On October 4, Doctor Braun was appointed post surgeon at Fort Abercrombie. Stewart and LeBoutellier were paroled and Hand rapidly advanced, receiving an appointment as brigade surgeon on October 8. Potts was appointed post surgeon at Fort Snelling, and Foster served as commissary of subsistence with the rank of captain, a position which he held throughout the war. The state board for the examination of medical officers was now replaced by a federal board consisting of Dr. Gale of Minneapolis, Dr. Reiner of Marine, and Dr. Finch of Hastings. Dr. J. H. Murphy, of St. Anthony, on December 8 was appointed surgeon to the Fourth Regiment. On December 10, Hand telegraphed Morton to come at once as surgeon to the First Regiment. Hand, as brigade surgeon, was authorized to do this, but the appointment had to be confirmed by the governor. There was considerable opposition at home to Morton's appointment because he was a Democrat, but Hand assured the governor that Morton was capable, and asserted, in addition, that the men liked him. It would seem that every man in Minnesota who had a following attempted to raise a company of troops; among them was Doctor Rosenk, who wished the authority to recruit an artillery company. He stated that he had served two years in Russia and nine years in the Prussian artillery. George McDonald Lambert, who had been in the drug business, received an appointment as hospital steward in the Fourth Regiment. He was a son of Judge Lambert.

Apparently but two new physicians came to Saint Paul this year. They were Professor C. D. Williams, late of the Western College of Homeopathy at Cleveland, Ohio, who went into partnership with Dr. Wm. Caine; and a Dr. Adams, also a homeopath. In January, 1861, a Dr. D. B. Reid came to Saint Paul for his health and gave a series of lectures on practical chemistry. The Saint Paul Academy of Medicine and Surgery gave him the use of their rooms and laboratory for this purpose. More shall be said of Dr. Reid later.

The *Pioneer* for April 9 contains an item of considerable interest which deserves to be quoted in full:

> The Annual Supper of the Saint Paul Academy of Medicine was attended last night by nearly all the practitioners in the city, with their guests, the Mayor and Aldermen and representatives of the Press. It was a most enjoyable occasion, to the guests at least, who found the prescriptions of the doctors not "bad to take" and productive of healthful exhilaration.

In April the Christ Church Orphans Home and Hospital was reopened, having been closed for a short period; Dr. Brisbine and Dr. F. R. Smith constituted the medical staff. The papers, early in the year, announced that there was considerable hydrophobia among dogs in the southern part of the State; in May the disease reached Saint Paul and an order was issued to destroy all stray dogs. This order seems to have been effectively carried out and we hear no more of rabies in the city. In the early autumn Judge Lambert complained to the authorities that the Indians were killing large numbers of deer about White Bear Lake in violation of game laws.

(To be continued in March issue)

President's Letter

THE program of the month on pneumonia received a surprising number of requests for additional information. February will deal with Pediatrics in general and especially with acute upper respiratory diseases, immunization and winter diets for children. In Minnesota we want to continue to emphasize the fact that high scientific standards and advancement of the public health combined, constitute our prime consideration. During the past month, however, we have turned our attention to social and economic phases also, and especially to government medicine. On January 14, an informative meeting was held where the workings of government medicine as it exists in European countries and in our neighboring state of South Dakota were portrayed by Mr. J. G. Crownhart, Madison, Executive Secretary of the State Medical Society of Wisconsin and Dr. B. A. Dyar of Pierre, South Dakota, Secretary of the Allied Professional Council, followed by Dr. C. B. Wright, Minneapolis, Dr. W. A. O'Brien, Minneapolis, Dr. A. Kuhlmann, Melrose and Dr. J. M. Hayes, Minneapolis. Dr. Gilbert Cottam, Minneapolis, opened the meeting with a talk on Americanism. Questions were raised by Dr. W. A. Coventry, Duluth, Dr. C. L. Oppegaard, Crookston, Dr. I. L. Oliver, Graceville, Dr. A. K. Stratte, Pine City and others.

The meeting gave us a picture of the problems involved in government and socialized medicine. Some felt that it struck a pessimistic note since no definite counter-program was suggested, but there was no time on this occasion for more than a factual presentation.

In Minnesota, experiments with group hospitalization insurance, a form of socialized medicine, are already underway. Private hospital insurance is also having a considerable sale. Many think that extensive hospital insurance would care for a large part of the immediate problem of the cost of illness and that if hospital service can be provided, other medical costs can be adjusted.

So far as insurance for medical care is concerned there are, after all, only a few methods of operation. One is by outside insurance companies. Another is by county or other local medical groups who organize non-profit services for their communities. Such services are being developed now in Cleveland, Michigan, Utah, Denver, California and New York. In our neighboring state of Wisconsin, in Douglas County, in which Superior is located, one of three experiments has been authorized by the State Medical Society. According to the Douglas County plan for a certain fee per month, members of the county society are going to attempt to give medical service to a local coöperative group. A third is by benefit societies, which have tried from time to time to provide medical services, including those in Los Angeles, Arkansas and other places that we have read about so extensively. Fourth, there is compulsory government health insurance.

Enumerations such as this simply call to our attention the tremendous amount of study needed. Realizing the difficulties involved, any proposed changes in our present system will be most carefully weighed by the profession of Minnesota.

Perhaps the continued orderly development and extension of services may continue here in the future as in the past, particularly as public health statistics prove Minnesota has achieved a place at the top. Certainly Minnesota, less than any other state, needs a radical change in its system of medical care.

OXYGEN IN AVIATION AND THERAPEUTICS

AS THE result of the work of numerous investigators, especially that of Barach[3] at the Presbyterian Hospital in New York, of Boothby[5] at the Mayo Clinic and of Waters[12] at the University of Wisconsin, oxygen has been used more and more extensively in the past few years for the treatment of anoxemia due to deficient saturation of the hemoglobin with oxygen from the lungs. Such anoxemia occurs in pneumonia, pulmonary edema and certain types of congestive heart failure. However, relatively scant attention has been paid to the use of oxygen in the treatment of anoxemia resulting from four other conditions. The first of these is the deficiency in mass of available oxygen that arises from diminution of physiologically efficient hemoglobin. Such diminution occurs in all types of anemia. In the second of the four conditions, anoxemia results from defective circulation; that is, the passage of blood through the capillaries is so slow that the oxygen is used up to an excessive extent. This state occurs in severe hemorrhage, surgical shock and certain types of heart disease. Third is histotoxic anoxemia wherein even if the pressure of oxygen in the tissues is normal, the cells cannot take up and use the oxygen; examples are poisoning from hydrocyanic acid, cyanide or alcohol. The fourth condition in which high concentration of oxygen is beneficial is in the treatment of patients suffering from the results of infection with an anaërobic or semi-anaërobic type of organism, as, for example, gas gangrene, in which local anoxemia is always present.

The extent of the damage to important organs and the possibility of this damage being repaired depends directly on the severity and duration of the lack of oxygen. Consequently, administration of oxygen must be started early and be continued for as long as is indicated, not only to ward off the cause of harm to the patient but also to give the body time to recover from the original cause of oxygen want or to give it time for adaptation.

The common clinical signs of lack of oxygen are cyanosis, which may be absent in anemia and often is difficult to perceive; a respiratory rate higher than 30 per minute; orthopnea and Cheyne-Stokes breathing; an increased pulse rate and restlessness and mild delirium. The clinical criterion of successful administration of oxygen is gradual disappearance of the foregoing signs.

The effects of lack of oxygen in disease are similar to its effects at high altitudes such as can be reached in airplanes. As a consequence of the rapid development of commercial and military aviation during the past decade there has been an increasing number of flights of several hours' duration, at altitudes above the critical point of

10,700 feet. Barach,[2] in his paper, "Pilot Error and Oxygen Want," emphasized the dangers that could arise from the anoxemia to which normal individuals are known to be susceptible at such altitudes; he pointed out, also, the possibility of accidents resulting therefrom. Armstrong and Heim found that exposure of normal subjects to a simulated altitude of 12,000 feet for four hours daily for twenty-six days produced concurrent mental and physical fatigue after each exposure, that these signs persisted for twenty-four hours and that they were manifested by difficulty in concentration, retention of ideas and attention over periods of time in excess of a few minutes. There was no evidence of acclimatization. Boothby and Lovelace[7] set the critical level at which a normal individual begins to suffer from tissue anoxemia at only 10,700 feet because at this point an appreciable decrease becomes manifest in the oxygen saturation of the hemoglobin of the arterial blood. Passengers with known, or perhaps unknown, cardiac or respiratory disease can experience serious or even dangerous evidence of anoxemia at much lower elevations.

One of the difficulties in supplying oxygen to counteract the effects either of high altitude or of disease has been lack of apparatus to deliver oxygen efficiently and economically. Boothby and Lovelace[7, 10] and Bulbulian recently have contributed to solution of these difficulties. They have designed a simple and efficient apparatus now known as the "B.L.B. inhalation apparatus." It consists, in part, of a nasal or oronasal type of mask and a reservoir-rebreathing bag. This device makes it possible to supply oxygen to both pilots and passengers and to maintain them at sea level conditions with a very small flow of oxygen. The apparatus has been found satisfactory and practical by flight tests made on commercial airlines, by several noted pilots, and at the Army Physiologic Research Laboratory at Wright Field in Dayton, Ohio, to a simulated altitude of 35,000 feet. The apparatus is equally applicable for the therapeutic administration of any desired concentration of oxygen up to 100 per cent and also for administration of any desired concentration of helium and oxygen mixtures. The cost of administering 50 to 60 per cent oxygen with this apparatus is about a fifth of what it is with the ordinary oxygen tent.

Possession of an efficient and economical apparatus for administration of gases stimulated Boothby and Lovelace[6, 7] to take up again work which once had been a major interest of the senior investigator. They confirmed the work of Fine and his co-workers that, in the majority of cases, the inhalation of 100 per cent oxygen would decompress the distended abdomen within twelve to twenty-four hours. However, they found that much better results were obtained when oxygen therapy was used in conjunction with Wangensteen's method of suction or drainage, employing the Miller-Abbot tube. In addition, they confirmed the work in which Fine and his associates demonstrated that the intense headache which ordinarily follows encephalography can be alleviated in about 80 per cent of cases by inhalation of pure oxygen for four to six hours. No ill effects have been observed as a result of breathing pure oxygen for as long as two days. On account of the possibility of pulmonary irritation from long continued administration of high concentrations of oxygen, it should not be used continually for longer than two days.

The inhalation of 100 per cent oxygen reduces the nitrogen partial pressure in the lungs to practically zero and, as a result, the nitrogen in the blood diffuses into the alveoli and is then expired, since gases always diffuse from a region with a higher pressure to a region of lower pressure of the particular gas. In the same fashion the resulting reduced partial pressure of nitrogen in the blood allows this gas to diffuse more rapidly from any body cavity, such as the intestines, subarachnoid space and ventricles, into the blood and thence into the alveoli of the lungs. Behnke and his co-workers have shown that 99 per cent of the nitrogen normally present in the body is eliminated in nine hours and a little more than 90 per cent in four hours. Inhalation of pure oxygen causes the hemoglobin to be completely saturated instead of only 95 per cent saturated. In addition, the amount of oxygen in simple solution will be increased about seven times. The combination of these two factors results in a 10 to 15 per cent increase in the amount of oxygen in the arterial blood.

The use of 100 per cent oxygen as an adjunct in the treatment of surgical shock was advocated by Boothby[6] and Lovelace[10] because of this increase of 10 to 15 per cent of oxygen in the circulating blood and an even greater increase in the oxygen pressure in regions where local anoxemia has resulted from edema or stasis. Moon defined shock as "a circulatory deficiency, neither cardiac nor vasomotor in origin, characterized by decreased blood volume, decreased cardiac output and by increased concentration of the blood." He stated, further, that anoxia of the blood and tissues is a factor of utmost gravity in the operation of the vicious circle associated with shock.

Since transfusion of blood is often given in surgical shock to increase the oxygen-carrying power of the blood, and as a means of increasing the circulating blood volume and of elevating the arterial pressure, Boothby[6] and Lovelace[10] suggested that the combination of blood transfusion and inhalation of 100 per cent oxygen almost always would be indicated in the treatment of severe shock, since both measures increase the oxygen-carrying power of the blood. They have reported cases of mild surgical shock in which great benefit followed inhalation of 100 per cent oxygen without transfusion.

Mann and his associates have demonstrated that placing an etherized animal in the shock position increases the blood flow in the carotid artery 30 per cent; this would seem to explain why there is often an almost immediate improvement in the mental condition of a patient in shock when placed in such a position because of the increased oxygen pressure thereby produced in the cerebral tissues by the increased rate of blood flow. Other conditions treated with apparent benefit by the use of high concentrations of oxygen have been gas gangrene, tetanus, acute coronary thrombosis in its early stages, angina pectoris, pulmonary embolism, massive atelectasis and acute alcoholism. Several patients with migraine have been benefited by the inhalation of pure oxygen, according to Lovelace. When there is moderate to severe secondary anemia and it is necessary to carry out a major surgical procedure, it is advisable to administer oxygen postoperatively in order to decrease the demand on the circulatory system and to prevent localized anoxemia at the site of operation.

Because of the circulatory disturbance and anoxemia associated with seasickness, Boothby, in coöperation with Goulden, surgeon of the Canadian National Steamship Company, recently tried out the value of 100 per cent oxygen in four cases. The greenish ashen pallor, so characteristic of the seasick patient, disappeared immediately in all of the cases and marked relief, amounting to practical disappearance of vertigo, nausea and vomiting, was effected in three of four cases; there was only slight improvement in the nausea and vomiting in the fourth case although the patient "felt better."

With the B.L.B. apparatus, treatment of patients who have mild or severe asthma with helium and oxygen mixtures is rendered practicable, efficient and relatively economical. The helium and oxygen mixtures are also of great aid in the treatment of patients with severe emphysema and pulmonary fibrosis, acute pulmonary edema and all mechanical types of respiratory obstruction in the trachea and bronchi. Tracheotomy sometimes can be avoided.

W. Randolph Lovelace, II, M.D.

SENSITIVITY TO SULFANILAMIDE

VALUABLE, yes, even life-saving as sulfanilamide has proven itself to be in the treatment of a variety of infections, it cannot be too strongly emphasized that an appreciable percentage of individuals show a sensitivity to the drug.

It is not uncommon for symptoms such as malaise, headache, nausea, diarrhea, and cyanosis to make their appearance. With discontinuance of the drug, there is a rapid disappearance of symptoms.

Reports have appeared, however, of more severe symptoms resulting from sensitivity to the drug. High fever with or without chills, hemolytic anemia rapidly appearing after a day or two of medication, agranulocytosis and jaundice have been reported.

It is important, therefore, that patients be seen daily while sulfanilamide is being administered. Fortunately, the drug is rapidly eliminated through the kidneys, and most patients recover promptly from effects of the drug.

Certain precautions in the use of sulfanilamide may be emphasized. The drug should not be given to patients suffering from nephritis or liver disease. It should be administered with sodium bicarbonate to compensate for the increased elimination of sodium by the kidneys and to minimize the development of acidosis, which sometimes appears. Magnesium sulphate should not be given a patient receiving sulfanilamide, as it favors the production of sulfhemoglobinemia. Cathartics and excessive fluid intake, of course, minimize the effect of the drug.

Sulfanilamide is the name given by the Council on Pharmacy for paramino-benzene-sulfonamide. It is the same preparation as that which came out first as prontolin. Prontosil is a 2.5 per cent solution of an allied drug of complicated formula, supplied for parenteral administration. The name neoprontosil is now used to designate the preparation of prontosil, which is supplied not only in solution for parenteral injection but also in five-grain tablets for oral use. Neoprontosil is said to be less toxic and as effective as sulfanilamide in similar doses, although it gives off only a small percentage of sulfanilamide in the tissues. It is, therefore, concluded that its effectiveness is not entirely due to its sulfanilamide content.

It can be safely said that the addition of sulfanilamide to our armamentarium marks a milestone in the progress of therapeutics. This drug, however, must be used with caution.

TOPICS OF THE MONTHS

IN OUR December issue we mentioned editorially the proposal of our new president, Dr. George Earl, to institute a combined preventive medicine campaign in Minnesota of lay and professional education, known as the "Indiana Plan." The proposal having met with the approval of the officers of the component societies, and the various committees of the State Medical Association, the various agencies will presumably join in the combined attack. It will undoubtedly take some time for the program to get in full swing. The journal will coöperate as far as possible in emphasizing in successive numbers the subjects chosen.

January—Pneumonia and Respiratory Diseases
February—Pediatrics
March—Degenerative and Circulatory Diseases (including heart and kidney disease and diabetes)
April—Cancer
May—Obstetrics and Gynecology
June—State Board of Health
July—University Hospital
August—State Board of Control
September—Traumatic Surgery (including highway accidents, first aid, et cetera)
October—Syphilis and Gonorrhea
November—Tuberculosis and Respiratory Diseases
December—Anemia and Deficiency Diseases (including vitamin therapy).

POISON GAS

AT the Peace Congress held at The Hague in 1907 the subject of the employment of poisonous gases in warfare was discussed very thoroughly and the decision was finally reached that this method of warfare was inhumane and against the laws of civilization. There was but one dissentient and that was our own representative, Captain A. T. Mahan, U.S. N. retired, who gave reasons for his objections in terms which since, in the light of later experience, have proved to be thoroughly justified.

When the German Army first used gas in the form of chlorine in a surprise attack against a division of French Colonials brigaded with Canadians at the second battle of Ypres in 1915 the world was horrified but before long both sides were straining their ingenuity to find more potent and efficient gases and these were used freely, chiefly in artillery bombardment, up to the end of the war. The chemicals found most useful in producing casualties were phosgene gas and the so-called "mustard," a heavy, volatile, oily liquid which emitted a peculiar smell suggestive of garlic or onions. Along with these were used tear and sneezing gases, principally for the purpose of interfering with the use of masks and thereby permitting the more lethal reagents to be inhaled.

Long before the close of the World War, military men and medical officers in all the armies became fully aware that the effects of these gases and chemicals had been greatly over-estimated. The immediate death rate among those exposed was very low and the ultimate after-effects practically negligible. The military value of Chemical Warfare, as it came to be designated in our army, consisted in its ability to upset the morale of troops and make temporary casualties of them. The French Colonials, mostly Senegalese, simply broke and ran in that first attack; the Canadians were able to hold their share of the line.

In our army the official figures covering all hospital admissions of battle injuries during our participation in the war show the following:

Total battle casualties hospitalized..	224,089
Of these, due to war gas, were......	70,552, or 31.4%
All others	153,537, or 68.6%
Deaths, war gas	1,221, or 8.9%
Deaths, all others	12,470, or 91.1%

After the war a very thorough investigation of the whole subject was made by the Chemical Warfare Service, the Surgeon General's Office and the Medical Research Laboratories of the Edgewood Arsenal, Maryland. The results of this study, as well as a summary of the reports of the British, French, German and Polish authorities, are set forth in *Army Medical Bulletin* Number 16 published in 1925 at the Medical Field Service School, Carlisle Barracks, Pennsylvania, in 115 pages. The conclusions, epitomized by Colonel H. L. Gilchrist, Director of the Chemical Warfare Service, himself a medical officer, are worth quoting: "The results attributed to the effects of warfare gases have been greatly exaggerated and this weapon is credited with more dire iniquities than have ever been associated with any other war weapon. . . . From the evidence thus far obtained it seems to be the consensus of opinion among medical men, not only in this country but also in Europe, that as a general rule there are comparatively few after-effects of warfare gases." The magazine *Time* recently quoted Dr. Francis Arthur Freeth, chief research chemist of Britain's Imperial Chemical Industries, as saying: "The amount of nonsense talked about poison gas is beyond belief."

All of which goes to indicate that there is no basis whatever for any undue excitement, much less hysteria, over any widespread danger from attack by poison gas.—G.C.

TUBERCULOSIS RESEARCH

APPROPRIATIONS for research in the study of tuberculosis during the coming year have been made to six leading universities in various parts of the country by the National Tuberculosis Association, according to an announcement received by the Minnesota Public Health Association from Dr. William Charles White, chairman of the Medical Research Committee. One hospital, Mt. Zion in San Francisco, California, also receives an appropriation for special laboratory work. This research is but one phase of the program financed by the National Tuberculosis Association's share of the five per cent of the funds raised through the sale of Christmas Seals in each state.

"Yale, Columbia, Cornell, Vanderbilt, Pennsylvania and Wisconsin universities will coöperate with us in our endeavor to achieve our final goal, the eradication of tuberculosis," said Dr. White. "Medical research will continue to be one of the strongest battle-lines against tuberculosis in 1939."

Two projects are now under way at Yale. Further study of the chemistry of the tubercle bacillus, the germ which causes tuberculosis, is being conducted by Dr. R. J. Anderson of the Department of Chemistry. Dr. Robert Thomas is in charge of another which deals with the physiological aspects of the substances of the tubercle bacillus.

The University of Wisconsin, under Dr. Horace Getz, will pursue research to determine the ingredients of cod liver oil which make it valuable in the treatment of tuberculosis. At Cornell, the biology of the tubercle bacillus inside living cells will be studied microscopically by Dr. Morton C. Kahn.

At Henry Phipps Institute of the University of Pennsylvania, further study of tuberculin will be continued with a view to establishing a more completely standardized product. Dr. Florence B. Seibert, recipient of the Trudeau Medal in 1938, is working on this project. The Moore School of Electrical Engineering of the University of Pennsylvania, under Dr.

F. Maurice McPhedran and Prof. Charles Weyl, is engaged in the improvement of x-ray technic.

It has long been known that in diabetics, tuberculosis runs a rapid and intensive course. Research to learn the causes back of this relationship will be conducted by Dr. M. Maxim Steinbach of the Columbia University Medical School. Dr. Steinbach will also direct his efforts to a study of increased susceptibility to tuberculosis during puberty and among schizophrenics. The chemistry of the proteins and carbohydrates which are contained in the tubercle bacillus will also be taken up at Columbia by Dr. Michael Heidelberger.

A joint study on the causes of calcifications appearing in x-ray plates in the human lung, which resemble those found in healed tuberculous lesions, will be conducted at Vanderbilt University under the direction of Dr. Henry C. Sweany.

Dr. Charles Weiss of Mt. Zion Hospital in San-Francisco will correlate findings in that institution on the active chemical principles in the white blood cells found in pleural fluid.

This program, which benefits every state through the development of new knowledge and technic for fighting tuberculosis, is but one phase of the program of the National Tuberculosis Association financed through the five per cent of the Christmas Seal sale received from each state. In Minnesota, the ninety-five per cent of the proceeds of the seal sale retained in the state makes possible specific projects in each county and a far-reaching state-wide program, including tuberculin testing and x-ray surveys of school children, sanatorium follow-up nursing service, health inspection and medical examination of school children, clinics, short courses on tuberculosis and x-ray consultation service for doctors, and an extensive campaign of child and adult education.

The Interstate Service

The Bureau of Investigation of the American Medical Association reports that a concern known as the Interstate Service at 111 West Jackson Boulevard, Chicago, appears to be writing to physicians with the hope of developing private prescriptions into nostrums. Part of the promotional letter reads:

> "How often have you thought of a favorite and unusually effective prescription that you would like to make available to the general public? One that could take its place with many of the proprietary preparations now generally on sale. . . . Let each specialist keep within his field. And only by collaboration can the greatest good be achieved. We address you, a physician, as specialists in the field of mail-order selling. And, as such, we say that the cost of launching such a venture is moderate. You provide the formula. It is our business to help sell it for you."

No reputable physician would, of course, lend his services, knowledge or personal treatment to such a performance. It is a peculiar form of stupidity that would lead a promoter to put out such an appeal at a time just after the new Wheeler-Lea and Food and Drug legislation have been passed. (J.A.M.A., Dec. 24, 1938, p. 2409.)

In Memoriam

Lewis Nelson Klove

1872-1938

DR. LEWIS N. KLOVE, a resident of Minneapolis for many years, died in November of a heart affliction at the age of sixty-six.

Dr. Klove was born May 22, 1872, at Northwood, Iowa, of Quaker stock. He attended Grinnell College, Iowa, and received his M.D. from the University of Minnesota Medical School in 1903. After taking his interneship at the Swedish Hospital in Minneapolis, Dr. Klove practiced for several years in Minneapolis. He then practiced for seven years in Wanamingo, three years in Chokio, and later in Kensington and Wright, all located in Minnesota, returning to continue practice in Minneapolis in 1929.

Surviving him are his wife, Celia, whom he married on June 8, 1910, and two sisters, Mrs. Ed. Thone of Kindred, N. D., and Mrs. Ida Stewart of Missouri.

Irving C. MacDonald

1874-1938

DR. IRVING C. MACDONALD was born in Minneapolis, Minnesota, on March 16, 1874. He attended the grade schools in Minneapolis and then moved to Grand Forks, North Dakota, where he received his high school education, as well as his college education at the University of North Dakota. He was principal of the Buckston High School from 1895 to 1898. He gave up this position to enter the University of Minnesota Medical School from which he graduated in 1902. After completing his year of interneship at St. Barnabas Hospital he located in North East Minneapolis.

In 1920, Dr. MacDonald married Miss Agnes Smith. In 1930, he moved his office to the Medical Arts Building where he practiced up to the time of his death. He had been a member of the Staff of St. Barnabas Hospital for over twenty years and was Chief of Staff two years ago. He was a physician for the Northern Pacific Railway for a number of years. He was a member of the Hennepin County Medical Society, American Medical Association, Alpha Kappa Kappa, Masons, Scottish Rite, and Shriners, also a member of the Lafayette Club. He was a member of the Presbyterian Church.

Dr. MacDonald had not been very well the last few years of his life. He was taken sick late Sunday, December 3rd, 1938, and died Monday night at 11:30 p. m. He was partly conscious for a few hours only.

Dr. MacDonald was a conscientious and trustworthy physician with good judgment and his patients had great confidence in him. He was particularly skilled in obstetrical work having attended over 3,400 confinement cases during his years of practice, and lost but two mothers during this time. He began his practice in the horse and buggy days and drove a good team. He was always equipped and ready to respond to any emergency calls night or day. When the autos appeared on the streets of Minneapolis, he was one of the first to recognize their value as a means of transportation for physicians and purchased one of the contraptions, a Ford Car, No. 916, the first of that make in the state.

Dr. MacDonald was sociable and well liked by his conferrers, even tempered, agreeable, and enjoyed a good story. We will all miss his company. We have lost a friend and his patients a good physician.

Dr. MacDonald was sixty-four years of age at the time of his death. He is survived by his wife Agnes, and son John, aged seventeen.—A. E. Benjamin.

Lewis K. Onsgard

1866-1938

Dr. LEWIS K. ONSGARD, a physician for the past forty-six years in Houston, Minnesota, died October 24, 1938, following a ten years' illness.

Dr. Onsgard was born near Spring Grove, Minnesota, January 1, 1866. He was reared on his parents' farm, educated in the public school, and attended the Eclectic Medical College at Cincinnati, Ohio, from which he obtained his medical degree when he was twenty-one years old.

After practicing five years in Harmony, Minnesota, Dr. Onsgard moved to Houston. On May 20, 1889, he was married to Miss Anna Laugen of Houston. He began his practice before the days of hard-surfaced roads and high-powered autos and his days and nights were filled with driving about on the country roads in bad and good weather. He untiringly gave of his ability for the welfare and improvement of his community. He served for many years as member of the board of health and coroner.

Dr. Onsgard was a charter and affiliate member of the Houston-Fillmore Medical Club, a member of the Olmsted-Houston-Fillmore-Dodge County Medical Society, the Minnesota Medical Association and the American Medical Association. He was an affiliate member of the Minnesota State Medical Association and Congress of Railroad Surgeons. Early in his career he was appointed as company surgeon for the Chicago, Milwaukee, St. Paul and Pacific Railroad Company and remained the company surgeon until his death.

Surviving Dr. Onsgard, in addition to his widow, are two sons, Orrin Onsgard and Dr. L. Kenneth Onsgard, who has his father's practice in Houston; three daughters, Agnes Onsgard of Houston, Mrs. A. M. Hanson of Albert Lea, and Mrs. P. F. Johnson of Houston; a brother, Martin Onsgard of Spring Grove, Minnesota; and a sister, Mrs. T. Jensen of Spring Grove.

Jerome F. Smersh

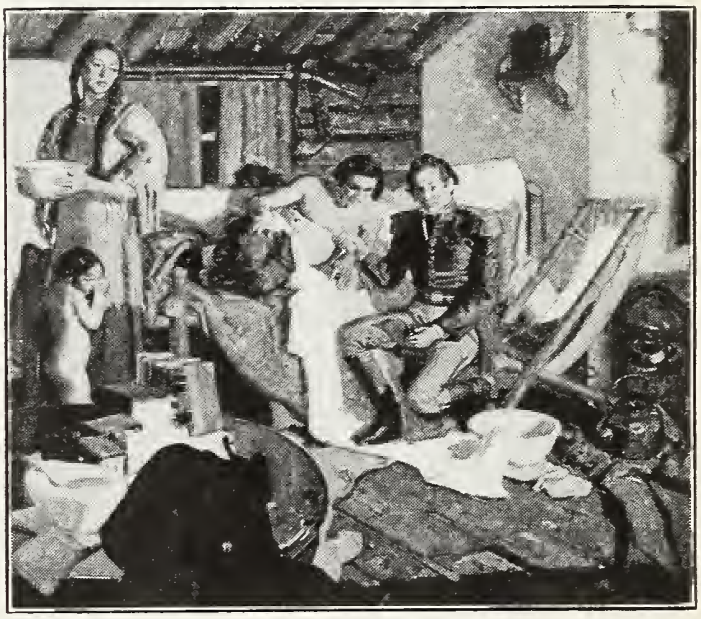
1892-1938

Dr. J. F. SMERSH, of Owatonna, died from pneumonia, October 27, 1938. A native of Owatonna and the son of the late Dr. Frank M. Smersh, he had carried on an active surgical practice there since May, 1919.

Dr. Smersh was born September 30, 1892, attended the public schools of Owatonna, and graduated from the Owatonna High School in 1911. He received his medical degree from the University of Minnesota medical school in 1917, and served his internship at the Ancker Hospital the following year. Entering the service, he spent a year as surgeon in the United States naval base hospital at Great Lakes, Illinois, attaining the rank of lieutenant, senior grade.

Dr. Smersh became president of the Board of Health of Owatonna in March, 1936, and was still serving at the time of his death. He became a member of the American College of Surgeons in October, 1936.

Dr. Smersh was married April 12, 1921, to Miss Ann Dapper of Faribault. Two sons, Jerome and Thomas, and a daughter, Rita, as well as his widow, survive; also his mother, who lives in Owatonna, a brother, Clement, and a sister, Mrs. Herbert E. Clefton, of Minneapolis.



Beaumont and St. Martin

"Beaumont and St. Martin" is the first of six large paintings in oil memorializing "Pioneers of American Medicine" which artist Dean Cornwell will complete in the next few years. Others in the series are: Dr. Oliver Wendell Holmes, Dr. Ephraim McDowell, Dr. Crawford W. Long, Dr. William T. G. Morton, and Major Walter Reed, and one woman, Dorothea Lynde Dix who, while not a physician, stimulated physicians to study insanity and feeblemindedness.

Arrangements to supply physicians with free, full color reproductions of "Beaumont and St. Martin" without advertising, and suitable for framing, have been made with the owners, John Wyeth & Brother, of Philadelphia, Pa. Send your request to Minnesota Medicine, 604 National Bldg, Minneapolis, or 2642 University Ave., Saint Paul.

MEDICAL ECONOMICS

Edited by the Committee on Medical Economics
of the
Minnesota State Medical Association
W. F. Braasch, M.D., Chairman

COMPLETE THE SURVEY

The National Health Program is now before Congress. Will it be shaped to meet the actual needs of the American people? Or will it be an extravagant and burdensome piece of legislation based upon doubtful studies and mistaken statistics?

Much depends now upon the Study of Needs and Supply of Medical Care of the American Medical Association.

The final form 1-F went out to all members late in January. This form provides for another daily record of medical services for the week, February 5 to 11, inclusive. When it is complete it should be sent to the Bureau of Medical Economics, American Medical Association, 535 North Dearborn Street, Chicago, Illinois.

This is the conclusion of the Survey and it should be filled out conscientiously by every member. Tabulations MUST BE COMPLETED by March 1, for report to the House of Delegates of the American Medical Association.

Let's complete the job in Minnesota!

FORUM ON MEDICAL CARE

Three hundred and sixty physicians and a group of dentists, hospital executives and social welfare workers attended the Forum on Medical Care, Saturday, January 14, at the Saint Paul Hotel.

Excerpts from the important talks made by visitors at that meeting, by Mr. J. G. Crownhart, secretary of the State Medical Society of Wisconsin and by Dr. B. A. Dyar, Pierre, S. D., executive secretary of the Allied Professional Council in charge of medical and health services in South Dakota, follow:

"No Profit . . ."

Mr. Crownhart: There is no profit to the physician in promoting anything that is not good for the public health.

We must be assured before we adopt any new plans for the delivery of medical care that they will in truth benefit the health of the people.

Conflicting Reports

Many conflicting reports have been brought back from England, Germany, and other European countries concerning the benefits or lack of benefits of their sickness insurance systems. The reason for these differences appears to lie in the fact that each inquirer goes armed with introductions to different departments and officials. The labor leader bears introductions to labor leaders who see the situation from one point of view; the social worker goes to the social service department and gets another point of view; the physician to physicians and secures still another version. Furthermore, these European systems are no longer experiments. They are established systems of many years' history. It requires time and painstaking inquiry to get at all phases of them. What you learn in the last 15 minutes of an interview may entirely change the conception gained in the first hour.

Out of many interviews it became evident to me that certain definite factors are common to all government systems. Presumably they would characterize any government sickness insurance scheme that might be set up in the United States also.

Premiums Are Fixed

The first is that insurance premiums are fixed. A definite percentage is taken from the employe's wage, and from the employer's payroll. A definite amount is added by the government.

This is the fund then, that must provide for medical care when the employe is ill, for limited care and compensation to the permanently invalided; for compensation for wage loss during illness.

We sometimes hear that we can have the medical care in the United States without the wage loss compensation or compensation for the disabled. It is the opinion of the International Labor Commission at Geneva, however, that it is impossible to have one of these three without the others.

Thus, there is a fixed amount to cover a threefold demand; but medical care is not a fixed item. Physicians do not remain in a groove. They develop x-ray, for instance, for diagnosis and treatment; they develop serums for control of disease and fever therapy.

No Money to Provide

These procedures are socially cheap. They save lives, prevent disability, but they are initially expensive and they require an outlay never anticipated in fixing premiums. Consequently, there is no money to provide for them.

The Administrator is obliged to balance his books and he does so by ignoring advances in medicine. His problem is this: On the one hand there is a fixed sum of money; on the other hand there is an unknown demand for medical service. No one has any idea how many people will be sick.

The physician must supply the unknown demand at so much per person per year and he, rather than the government, is the real insurer against this demand.

He Stays by the Book

He is supplied for the purpose with the "book." The book is a special pharmacopeia for insured patients and it contains all of the drugs and amounts which he may officially prescribe for his panel patients. If he exceeds the amount indicated or if he prescribes a new and expensive drug he must explain his action to the Administrator. If the Administrator is not satisfied with the explanation—and often he is not—then he must explain it to the panel committee composed of laymen. If the committee is not satisfied, the physician must pay for the drugs himself. Disease does not stay in the book; but it is natural that most physicians should stay in the book if they wish to get along.

The second is that free choice of physician, though nominally allowed in many systems, means, only, that the patient may indicate his choice of names on the panel when he becomes insured. Under ordinary conditions his freedom of choice ends there and he must remain with the physician of his original selection.

Cost of Administration

Third: Insurance systems do not administer themselves. Even in England, known to have a fine concept of Civil Service, the cost of administering is 17 cents out of every sickness dollar. In all countries the cost runs from 17 to 20 per cent. Somebody must check the insurance rolls; somebody else must check the "book"; somebody else must check those who are reported sick to see if the sick man is really in bed and really needs the money. Somebody else must audit the accounts. Incidentally, this is how the sickness checkup sometimes works. Mr. B—has been sick with a bronchial ailment and is reported unable to work for another week. The checker goes to Mr. B—'s house, finds him working in his garden. The doctor says it's all right for Mr. B— to work in his garden; it's good for him; but Mr. B—is not yet well enough to go back to his work in one of the dusty trades. The Administrator fails to understand the distinction and the doctor dares not stand out against the Administrator. Mr. B— goes back to work.

One to Fifty

In all countries there is a least one employe to every 50 to 100 insured persons—in Wisconsin that would mean about 2,800 employes would be needed to administer a system for all employed persons.

Fourth: The Administrator inevitably becomes a trustee of funds and not, as one might expect, a guardian of the public health. He finds, at once, that every insured person wants "all that's coming to him"—and more. He knows, at the same time, that only about two per cent of the population is likely to be sick at any one time. On the one hand there is a heavy demand for care, some of it unnecessary—on the other is a fixed amount of money which must be made to cover all demands. His job becomes one of guarding his money, dogged always by the fear that it will not last the year.

It is noteworthy, at the same time, to contrast the headquarters of the sickness insurance administration in every country with most of the hospitals.

Ancient Hospitals

You see many hospitals where wonderful work is being done in spite of limited facilities in ancient buildings with old equipment. But the headquarters of the administrative system are new and modern in every respect.

At the Mercy of Parties

Fifth: The physicians are universally at the mercy of whatever political party may happen to be in power. In Vienna, I looked in vain for several noted physicians, most of them Aryans, famous physicians to whom I had been given letters of introduction. They had left Vienna; they would not be back. Why? Because they were not in sympathy with the Nazi party in power, and this was not exclusively a Nazi phenomenon. Nazi predecessors had banned other physicians before them. Sickness insurance systems cannot be separated from politics and government.

Sixth: Physicians are everywhere over-loaded. There is never time to give the individual patient all of the attention he needs.

"What Can You Learn?"

In an English teaching hospital where I spent several hours observing and asking questions, American-designed equipment and even American text books were being used. At the end of my visit, the chief of staff said to me: "And now may I be permitted to ask you a question? What is it that you, an American, can possibly learn from us?"

Medical care under European sickness insurance systems is a salvage service, only. There is neither time nor money for tracking down disease and opening up new fields.

Are we, then, to transfer these systems to America? Would they fit into our American scene?

Must Tell What It Means

That is for the people themselves to determine. The profession of medicine is only about 1000th of the population. Alone, you cannot hope to determine what the answer shall be.

Many proposals are being made today and the people know them by name, only. Their sponsors tell how the law might read. They do not tell what it means. The people must know what these proposals mean to them if they are to make a wise choice. You, the physicians, must tell them.

Doctors Were Leaving

Dr. Dyar: Some of the things we have done in South Dakota might be regarded as unorthodox; but we had a drought in South Dakota and we had to do unorthodox things to meet the conditions.

Many counties were so heavily in debt that they could not hope to handle their legal obligation to care for the sick. Many fine doctors were moving away because there were no patients left who could pay medical fees. Unless something could be done immediately, the majority of the people were going to be left without doctors or medical facilities.

Emergency Measures

Various emergency measures were tried in different localities. In one, funds were secured from the Children's Bureau to maintain a health unit, doctor, nurse and clerk, who provided medical care in the county. In another, aid was secured from the United States Public Health Service.

Farmers' Aid

The medical program of the Farm Security Administration began in May, 1937, with a Farmers' Aid Corporation organized to handle the funds turned over by the Administration for emergency medical care of its clients. At first, this service was available only to standard loan cases. Now, it is available to all who wish to join for $2 a month per farm family. Out of 40,000 farm family clients of the Farm Security Administration, 27,000 are members which means that about 135,000 are supplied with medical service.

The service is exclusively of an emergency nature. From November 1, when the service was re-organized, to the end of the government fiscal year, July 1, each family paid $16. One eighth of this amount was paid out each month for medical service. Any surplus above the need was pro-rated to participating doctors and dentists. The funds were paid out on the following scale: 51 per cent to physicians; 30 per cent to dentists; 15 per cent to hospitals; three per cent to pharmacists; one per cent to nurses (nursing care is not provided outside of the hospitals).

Difficulties

The administration of the service is complicated; we have had our difficulties.

First, with the doctors—A few of the doctors, knowing that they were going to get cash for their services, were not too particular to keep it to emergency care.

Unnecessary Services

Some rendered expensive and unnecessary service to cash in on the program. For instance, one sent a bill for six separate examinations and office calls (total $24), for treating six children in one farm home who had the itch.

Some, who operate small hospitals, unnecessarily hospitalized some cases, charging a hospital bill and $1 a call for each call.

Collecting Old Bills

Some used the program to collect old bills, moving the dates of old, unpaid-for services up to the date of the Farm Security program.

Occasionally, the doctor instructed the client to pay him direct, promising to reimburse the client if he collected from the Farm Aid Corporation.

Then there were difficulties with the clients—Some farmers attempted to cash in on the service immediately with new teeth and glasses neither of which were allowed. Some county commissioners, undoubtedly, promised farm clients any type of service including glasses, teeth and care for chronic ailments provided they joined.

Some clients refused to join until an acute illness arose and they needed expensive service.

Neurotic Shoppers

Some clients became neurotic medical shoppers, going from doctor to doctor just for the pleasure of having a physical examination.

The situation was made more difficult for the doctors and the Farmers' Aid Corporation by county commissioners who tried to lighten their load of indigent by sending relief cases to the Farmers' Aid Corporation.

Free Choice

Now, as to the good points of the program—There is no question but that some of our farm families are getting better care than they had before, especially in confinement cases.

The program is confined to the regularly licensed physicians.

Also the patient has free choice of physician.

Furthermore, many fine physicians have been enabled to remain in the state. If they had left, many less desirable practitioners, particularly foreigners who are constantly inquiring for opportunities, would have moved in.

Most of the doctors wish to continue the program even if they can collect only 50 per cent of their fees for the work they do.

For the future in South Dakota and anywhere else where such a program may be organized, I have these suggestions to make:

Suggestions

1. That all clients be given a physical examination before they are admitted to the service.
2. That the Farm Security Administration arrange for all clients to join so that costs can be spread.
3. That a limit be placed upon hospital days and medical service available through the program.

In theory, this is the best plan I have seen in operation anywhere for care of low income and border line farm families. Where doctors and clients are honest, it works.

MEDICAL POLICIES AND PROGRAMS

Programs and policies for 1939 of the various sub-committees of the Committee on Medical Economics were discussed by respective chairmen, at a meeting called January 4, by the general chairman, Dr. W. F. Braasch, Rochester.

As a result of this conference several changes in the general structure of the committee will be proposed to the Council at its next meeting. If the Council approves, another sub-committee devoted exclusively to the study of sickness insurance will be formed as part of the general committee. No such committee now exists in Minnesota and the need for it, as more and more plans are being formed and tried out elsewhere, is obvious.

Adding Industrial Health

Industrial health problems will be added, also, to the work of the Sub-committee on Industrial Relations, of which Dr. M. S. Henderson of Rochester is chairman. This committee has concerned itself, heretofore, with workman's compensation and relations with insurance companies. The new function is prompted by the increasing importance assumed by health problems of industry, recently signalized by a new committee on Industrial Health formed by the American Medical Association and also by the new program on industrial health which will be initiated by the State Department of Health in Minnesota if appropriations are made by the Legislature at this session.

To Avoid Overlapping

The usefulness of these occasional conferences of committee chairmen was clearly evident at the January meeting. All are dealing with matters of great moment to the medical profession in Minnesota; but their work must be evaluated periodically and brought into line with the working program of the association so that there will be no overlapping and so that no vital matters will be overlooked.

Talks to Small Groups

It was generally agreed that medical students are not sufficiently instructed in the vital details of their social and economic relations to fellow practitioners and to the public and that such instruction might well take the place of much of the detail work with which the curriculum is now crowded. It was suggested, however, that informal talks to fraternity and other small groups might be more effective than formal required lectures. Also, that the committee might function in assisting in the instruction of these speakers.

Promoting Interprofessional Relations

Chairman B. J. Branton, Willmar, of the Medical Advisory Sub-Committee, reported that there had been fewer malpractice cases, by half, during the past six months than in previous periods in Minnesota. This fine record is the result of three years of effort by the committee to promote a better sense of responsibility toward each other among the members of the association. Excellent relations with the bar association and with insurance companies were also reported by Doctor Branton. In this connection, a series of six interprofessional meetings throughout the state are being arranged by the committee in coöperation with the Interprofessional Relationships Committee, of which Dr. Savage of St. Paul is chairman. Lawyers, dentists, and physicians join in these meetings, the next one of which is scheduled for February 13 at the St. Paul Athletic Club.

For Farm Security Plan

The request made of the Council at its December meeting (see January issue Minnesota Medicine) for a medical service plan for Minnesota clients of the Farm Security Administration was at that time referred to the Sub-Committee on Low Income and Indigent Problems. Dr. W. A. Coventry, chairman, was not present at the conference but it was announced that a special meeting to study the proposal had already been called and that immediate consideration would be given to the matter.

It was the opinion of the chairmen present that the state association committee should not refuse to assist Farm Security Administration officials in the development of a plan in Minnesota since both Minnesota clients and their physicians would otherwise suffer. So far as the physician is concerned, in this case, the patient pays his own fees. The money is provided by loan from the Farm Security Administration.

Dissatisfaction

Doctor Henderson reported considerable dissatisfaction with the handling of industrial insurance cases because the choice of the patient is often ignored in the referral of industrial cases.

Dr. J. M. Hayes, Minneapolis, outlined the "gentleman's agreement" arrived at earlier with the Industrial Commission by which choice of the patient was to be recognized and fees paid.

It was suggested that another meeting be held with the commission soon to clarify the entire matter; also that a representative of the Minnesota Federation of Labor be present to convey to the commissioners Labor's declared preference for choice of physician in industrial medical practice.

Dr. George Earl, Saint Paul, President of the Minnesota State Medical Association, outlined the Association's 1939 "Co-ordinated Medical and Public Health Program" which begain with the January program of education on pneumonia prevention and control.

Real Problem

According to Doctor Earl, medical association representatives should establish it definitely that physicians are primarily interested in the health of the people. They recognize, of course, that medical costs have increased and they are carefully studying all proposals to ease economic burdens of sickness. In Minnesota, at least, medical care is better than average and above the level of other essentials, such as food and housing. The real problem lies with the man with the $100 a month income who feels that government care is the answer to his problems. For him, group hospital insurance can bring a major assistance in payment of costs of illness and, perhaps, no further experiments in sickness insurance should be tried while group hospital insurance is being developed and extended in Minnesota.

For Training Speakers

The Forum on Medical Care scheduled for January 14 in St. Paul was designed to assist in the training of all physicians in the intelligent discussion of the social and economic problems of medicine, with friends or patients and before the public. The question remains, Doctor Earl said in conclusion, how much shall these matters be stressed in public.

Dr. F. A. Olson of Minneapolis, chairman of the Sub-committee on Contract Practice, recalled that the American Medical Association was at one time opposed to helter-skelter discussion on the subject.

Dr. Buie was of the opinion that speakers should not be left to volunteers.

Must Be Prepared

"We are being called upon to speak," Doctor Braasch said, "and we must be prepared to respond. That means that we must be thoroughly well informed, that we must understand the lay point of view and be sympathetic toward it while we undertake to explain fully the issues involved.

"The Co-ordinated Medical and Health Program instituted for 1939 by the state association is a step in advance in our public relations and an excellent approach to education concerning the philosophy and standards of our American system of care."

COUNTY OFFICERS TO MEET

Important speakers and timely discussions will mark the 1939 program of the annual County Officers' Conference scheduled for Saturday, February 25, at the Saint Paul Hotel.

Round table breakfast discussions will begin at 8 a. m., and continue until 10. The Medical Survey, medical relief service under the "choice of vendor" legislation, group hospital insurance, medical care for Farm Security clients and membership will be discussed at this informal session.

A symposium on methods of public education will follow with outside experts in platform speaking, radio and newspapers as speakers.

Industrial hygiene and workmen's compensation will be the subject for a second symposium which rounds out the morning program. On this section of the program representatives of Labor, of the Industrial Commission and the insurance companies will talk; also the new program for industrial health contemplated by the State Department of Health will be outlined.

For the afternoon, the general subjects will be national and state legislation on health and medical problems. For these discussions, Dr. R. G. Leland, director of the Bureau of Medical Economics of the American Medical Association, will be present and representatives of both the House and Senate of the state legislature will talk.

The meeting comes at a time when the air is full of plans, rumors, public and private discussions on medical care. It provides a unique opportunity for discussion and exchange of information. Travelling expenses of one representative from each society will be paid as usual by the association. Every member is invited to attend, however, and all will be guests at luncheon.

AS ONE READS, SO ONE THINKS

(Monthly editorial prepared by the Medical Advisory Committee.)

Headlines in papers, sketches in magazines, editorial writers, and radio commentators depict the changing world. As the world thought and map changes, so medicine is an ever changing science. The books and procedures of ten years ago become obsolete in the new light of today. Progress cannot be stopped, and he who wishes to turn back the pages to yesterday finds himself lost in a maze.

But, fundamentally, the ideals of the medical profession are the same. Unselfish service to others has become a part of the life and being of the medical man. Monetary gain has been a secondary consideration; the wealthy physician is a rarity. Success in our work is not measured by material wealth but by the regard in which we are held by our clientele. This success depends, of course, to a great extent on natural ability; but, added to natural ability must be industry, integrity, and a clear, professional understanding of the problem at hand. The physician-patient relationship is a sacred thing which no amount of legislation can take away.

Your Medical Advisory Committee does believe, however, that the physician-physician relationship can be improved by closer and clearer understanding of the other physician's problems and less criticism of his work.

Study in post-graduate centers, fraternizing with those from a distance and attendance at society meetings of our own soon scatter the cobwebs in destructive thinking. Participation in programs and the writing of papers maintain up-to-dateness and equilibrium of ideas.

But, withal, one should not forget that we are citizens with specialized training entitled to the same protection afforded other citizens under the law and, as such, we have a clear right to the fruits of our labor in proportion to the time spent in preparation and the ability gained by the successful use of this preparation in the service of suffering humanity.

Happy is he who each day spins one more thread into the pattern of a successful life.

—B.J.B.

THE DOCTOR'S BILL

(Paragraphs from an important leading editorial which appeared in a recent issue of the *Chicago Tribune.*)

The indictment of the American Medical Association and some of its directing officials was not a courageous act in the sense that the Administration is likely to lose great numbers of votes as a result of its action. The probabilities, fortunately, are all the other way. . . .

When everybody else sends flowers, the doctor sends a bill. All too frequently it arrives when the family is hard-pressed because of loss of income resulting from the illness itself and because drugs, nursing, hospital care and special diets have imposed unexpected burdens upon the family budget. . . . Illness itself inspires in the victim and his family a sense of injustice. . . .

Accordingly, many citizens would welcome state or socialized medicine.

The medical association has resisted that trend with all the vigor at its command, believing that if doctors had to look to the government for support, the quality of medical service and the competence of the profession would decline rapidly.

The present administration in Washington is eager for new fields of activity to dominate. . . .

Whatever the faults of the present organization of medicine, the fact is that disease and death rates have dropped to the lowest point in the history of the country. Medical science has made phenomenal progress, thanks in no small part to the activity of the medical association. . . . Families of moderate means constitute the largest single element in the population. If their needs were not being met pretty satisfactorily now the death and disease rates would be rising, not falling.

The doctors have recently proposed a plan which deserves sympathetic study. They suggest that the risk of illness among persons of small income be covered by insurance with an annual premium which would not place an undue strain on the ordinary family's budget and which would cover ordinary risks. . . .

In spite of the fact that its material rewards are not great, medicine, today, attracts and holds superior young men and women; it would not do so if they felt that their future depended on governmental favor rather than personal attainments. Experience teaches that there is far more reason to place confidence in the high purpose and altruism of the doctors than in the tall talk of politicians or the wishful thinking of professional reformers.

NORTHWEST CONFERENCE

The annual Northwest Regional Conference takes on an especial importance this year as Congress awaits introduction of legislation embodying the National Health Program and as several state and county societies prepare to embark upon new experiments in prepayment plans for care of the sick.

The date selected is Sunday, February 12, one day in advance of the Annual Congress on Medical Education and Licensure. The place is the Palmer House, Chicago. The Missouri State Medical Association, of which Dr. Carl F. Vohs of St. Louis is president, is host society for the meeting.

Among program features of great interest will be reports on the new medical programs in Michigan and in California; a review of the legislative situation in Washington by Dr. R. G. Leland, director of the Bureau of Medican Economics of the American Medical Association, and a review of the progress to date of the Survey of Medical Needs and Supply, conducted all over the United States under the auspices of the American Medical Association, by Dr. W. F. Braasch of Rochester, chairman of the National Advisory Committee on the Survey.

All medical society officers and interested members are urged to attend this meeting.

Minnesota physicians will recall that the Northwest Regional Conference originated in Minnesota and was held for many years in Saint Paul, with the Minnesota State Medical Association as host. Removal to Chicago was occasioned by the participation of distant East Central states in the deliberations.

MINNESOTA STATE BOARD OF MEDICAL EXAMINERS

Windom Osteopath Fined $250.00 for Practicing Medicine Without License

Re: State of Minnesota vs. John L. Moore.

On December 22, 1938, John L. Moore, a licensed osteopath with offices at Windom, Minnesota, entered a plea of guilty to an information charging him with the crime of practicing medicine without a license. The Honorable Charles A. Flinn, Judge of the District Court at Windom, sentenced Moore to pay a fine of $250.00 and court costs of $7.00. Moore paid the fine and costs in preference to serving a jail sentence.

The complaint against Moore was filed by Mr. Brist on behalf of the State Board of Medical Examiners following an investigation which disclosed that Moore was prescribing and furnishing medicine for the internal use of patients. In the instant case Moore had furnished and administered an alleged cough medicine for a 2-year-old girl. The little girl suffered a burn on the side of her face when some of the medicine came in contact with her face following her refusal to take the medicine. The parents attribute the burn to the cough medicine. Moore then prescribed some medicine for the burn.

The Medical Board's investigation disclosed that Moore was writing prescriptions that were being filled at one of the local drug stores for medicines of various kinds, all of which were to be taken internally. The records of the Medical Board show that Moore was warned as far back as 1930 to confine his practice to osteopathy, for which he holds a license.

OF GENERAL INTEREST

Dr. John R. Black of Rochester was recently married to Miss Betty V. Hume of Anadarko, Oklahoma.

* * *

Dr. William L. Mackenzie King of Rochester was married recently to Miss Marjorie Rean of Toronto, Canada.

* * *

Dr. M. M. Hursh, formerly of Grand Rapids and Cohasset, has opened offices in Hibbing for the practice of medicine.

* * *

Pharmacists are forbidden by law to refill narcotic prescriptions. Complaints have reached the Minnesota State Medical Association through the Minnesota State Pharmaceutical Association that some physicians are forgetful of this provision of the Minnesota Narcotics Law. Physicians must not expect druggists to refill prescriptions containing narcotics.

Dr. H. S. Sherman, formerly of Plainview, has moved to Spring Valley, where he has opened offices for the practice of medicine.

* * *

Dr. L. E. Prickman of Rochester was inducted into office as president of the local Kiwanis Club for 1939, at a meeting held on December 29.

* * *

Dr. P. F. Sorum, formerly of Lumberport, West Virginia, has located in Jasper for the practice of medicine. Dr. Sorum is a graduate of the Rush Medical College in Chicago.

* * *

Dr. Richard A. Bardon of Duluth has been named chief of staff of the Miller Memorial Hospital for the current year. Dr. Philip Eckman is vice chief-of-staff, and Dr. Harold Hoff, secretary-treasurer.

* * *

Because agranulocytosis has been found to follow prolonged administration of amidopyrine containing drugs, the content of this drug in allonal has been replaced by three grains of acetophenetidin to the tablet.

* * *

Dr. M. G. Gillespie of Duluth was elected chief of staff of St. Mary's Hospital at its annual meeting recently. The principal speaker at the meeting was Dr. M. B. Visscher of the University of Minnesota department of physiology, who spoke on "The Growing Importance of Physiology to the Practice of Medicine."

Dr. A. H. Field has recently become a member of the state hospital medical staff, Fergus Falls. A graduate of Marquette university medical school, Dr. Field interned at St. Joseph's hospital in Saint Paul and at Fairview hospital in Minneapolis. Dr. Albert A. Bodaski of Minneapolis has also joined the staff.

* * *

Dr. A. M. Watson, who has been practicing in Royalton for thirty-four years, has taken his son, Dr. Sidney W. Watson, of Alexis, Ill., into partnership. Dr. Sidney Watson is a graduate of the Minnesota University medical school. He sold his practice at Alexis last fall where he had been located for more than four years.

* * *

A symposium on the "Public Health Significance of the Virus and Rickettsial Diseases" will be presented by the faculty of the Harvard School of Public Health June 12-17, 1939. Lectures will occupy five mornings and clinics and demonstrations will be given each afternoon. A fee of $25.00 will be charged. Further information may be obtained by writing the Secretary of the School of Public Health, 55 Shattuck Street, Boston.

* * *

The American Board of Obstetrics and Gynecology announces that the general oral, clinical and pathologic examinations for all candidates, Part II Examinations (Group A and B), will be conducted by the entire Board, meeting in St. Louis, Missouri, on May 15 and 16, 1939, immediately prior to the annual meeting of the American Medical Association.

Application blanks and booklets of information may be obtained from Dr. Paul Titus, Secretary, 1015 Highland Building, Pittsburgh (6), Pennsylvania.

* * *

The Council on Physical Therapy of the American Medical Association has a number of films illustrating the value of physical therapy methods which can be borrowed for educational use by medical societies. These films illustrate certain methods used in muscle training, occupational therapy, underwater exercises, massage, and present the effects on circulation of heat and cold and massage.

In addition, films on the subject of syphilis, cancer, blood transfusion, the physiology of labor, pneumonia, and the treatment of burns, are obtainable.

These films may be obtained by writing to the Director of Exhibits of the American Medical Association, the only cost entailed being the cost of transportation.

* * *

The American Board of Ophthalmology announces an important change in its method of examination of candidates for the Board's certificate.

Examinations will be divided into two parts. Candidates whose applications are accepted will be required to pass a *written* examination which will be held simultaneously in various cities throughout the country approximately 60 days prior to the date of the oral examination.

The *written* examination will include all of the subjects previously covered by the practical and oral examinations.

Oral examinations will be held at the time and place of the meeting of the American Medical Association and of the American Academy of Ophthalmology and Oto-Laryngology, and occasionally in connection with other important medical meetings. The *oral* examination will be on the following subjects: External Diseases, Ophthalmoscopy, Pathology, Refraction, Ocular Motility, Practical Surgery.

Only those candidates who pass the written examination and who have presented satisfactory case reports will be permitted to appear for the oral examination.

Examinations scheduled for 1939: *written*: March 15 and August 5. *Oral*: St. Louis, May 15; Chicago, October 6.

Applications for permission to take the written examination March 15 must be filed with the Secretary not later than February 15.

Application forms and detailed information should be secured at once from Dr. John Green, Secretary, 6830 Waterman Ave., St. Louis, Mo.

* * *

U. S. Navy Medical Corps

The Medical Corps of the United States Navy offers a number of internships and commissions to graduates of Class "A" medical schools who have completed or are about to complete an internship in a civilian hospital. Examinations will begin on Many 8, 1939, and applications should be on file at least one month prior to that date.

Qualified candidates who have completed internships in civilian hospitals and who successfully pass the competitive examination will be commissioned as Assistant Surgeons with the rank of Lieutenant (junior grade) and assigned to the Naval Medical School, Washington, D. C., for a postgraduate course of instruction prior to their assignment to sea or foreign shore duty.

Candidates must be United States citizens between the ages of 21 and 32 years at the time of appointment, and pass a physical and professional examination.

Officers of the rank of Lieutenant (junior grade) without dependents receive compensation of $2,699 per year, while those with dependents receive $3,158 per year. There are additional cash allowances.

If interested, write at once for further particulars to Bureau of Medicine and Surgery, Navy Department, Washington, D. C.

◆ REPORTS and ANNOUNCEMENTS ◆

MEDICAL BROADCAST FOR FEBRUARY

The Minnesota State Medical Association Morning Health Service

The Minnesota State Medical Association Broadcasts weekly at 11:00 o'clock every Saturday morning over Station WCCO, Minneapolis (810 kilocycles or 370.2 meters) and Station WLB, University of Minnesota (760 kilocycles or 395 meters).

Speaker: William A. O'Brien, M.D., Associate Professor of Pathology and Preventive Medicine, Medical School, University of Minnesota. The program for the month will be as follows:

February 4—Communicable Disease
February 11—Obedience in the Home
February 18—Physical Defects in Childhood
February 25—Children's Dentistry.

STATE MEETING

The program of the Minnesota State Medical Association's 86th annual meeting is now complete, according to a report just issued by the Committee on Scientific Assembly.

The meeting will be held May 31, June 1 and 2, at the Minneapolis Auditorium with business sessions of the Council and House of Delegates scheduled on the evening of May 30 in advance of the meeting.

Internal medicine, surgery, obstetrics and gynecology, urology, dermatology and radiology will be represented on the scientific program with eight distinguished out-of-state speakers, as well as members of the association, to address the sessions. Scientific sessions will be confined, for the first time, to two days of program time, Friday, June 2, being devoted exclusively to the second Congress of Allied Professions dealing with public health and the public relations of medicine.

Round table luncheons will be a feature of the scientific sessions on Wednesday and Thursday, May 31 and June 1. A series of ten or more luncheons is being planned, each on a separate subject. Attendance at these luncheons will be limited to twenty each in order to facilitate informal discussion.

The annual banquet, scheduled for Thursday night, and also hotel headquarters for the meeting will be at the Curtis hotel.

Physicians from all of the nearby states will be invited to attend the meeting, which constitutes the only major medical gathering in the Northwest this year. Dentists, hospital administrators, nurses, technicians, welfare workers and all others who are in any way concerned with the delivery of medical services will be invited to the congress on Friday.

Members of the committee in charge of the program are: Dr. B. B. Souster, and Dr. Allen Wilson, Saint Paul; Dr. V. S. Counsellor, Rochester; Dr. F. H. Magney, Duluth; Dr. Charles Bolsta, Ortonville; Dr. B. O. Mork, Jr., Worthington; Dr. J. A. Myers, Minneapolis; Dr. W. A. O'Brien, University of Minnesota, Dr. George Earl, Saint Paul; Dr. J. M. Hayes, Minneapolis, and Mr. R. R. Rosell, Saint Paul. Dr. A. E. Cardle, Minneapolis, is chairman of the Committee on Local Arrangements.

AMERICAN CONGRESS IN OBSTETRICS AND GYNECOLOGY

The first Congress of Obstetrics and Gynecology will meet in Cleveland, Ohio, September 11-15, 1939, and will be sponsored by the American Committee on Maternal Welfare, Inc., of which Dr. Fred Adair is chairman.

Sessions will occupy mornings, afternoons, and evenings of the five days of the Congress and various phases of the subject of human reproduction will be handled. This will include medical care from the standpoint of the general practitioner, specialist and educator, obstetric nursing, obstetrics from the standpoint of public health and the institutional administrator.

Those wishing to attend should communicate with the American Congress of Obstetrics and Gynecology Headquarters, The Annex, 650 Rush Street, Chicago, Illinois.

BLUE EARTH COUNTY SOCIETY

Dr. G. A. Liedloff of Mankato was elected president of the Blue Earth County Medical Society for 1939, at the annual meeting of the Society held late in December at the Mankato Clinic. Dr. R. K. Edwards of Elysian was elected vice president, and Dr. C. A. Koenigsberger of Mankato was elected secretary.

WASHINGTON COUNTY

At the January meeting of the Washington County Medical Society, Dr. D. Greth Gardiner of Saint Paul presented a very interesting lecture on bronchoscopy. The lecture was illustrated by x-ray plates on which the pathologic changes were clearly indicated and explained by Dr. Gardiner. After this lecture the Society indulged in comments on welfare work and the compulsory insurance which the federal government is trying to force upon us. Hospital insurance, both commercial and non-profit in character, came up for consideration, as did also the meeting at the Saint Paul Hotel on January 14.

WINONA COUNTY SOCIETY

The annual dinner and meeting of the Winona County Medical Society was held on Monday evening, January 9, at the Hotel Winona.

About forty persons attended the dinner, which was followed by a talk by Dr. Lewis G. Jacobs, roentgenologist at the Winona General Hospital, on "Therapy of Cancer of the Breast," and a talk by Dr. John Tweedy of Winona on "Chronic Abdomen and Its Relation to the Abdominal Triad."

Dr. R. L. Page of St. Charles was elected president; Dr. William Von Rohr Heise of Winona was elected vice president, and Dr. H. J. Roemer of Winona was elected treasurer. Dr. I. W. Steiner of Winona was re-elected secretary.

Members of the Auxiliary were entertained at dinner at the hotel, by the Society. Following the dinner, a meeting was held at the home of Mrs. Robert Tweedy. About fifteen members were present.

ST. JOSEPH CLINICAL SOCIETY

The St. Joseph Clinical Society, St. Joseph, Missouri, will hold its eighth annual spring clinic on March 28 and 29, at the Hotel Robideaux, St. Joseph, Mo. There will be no registration fee. The purpose of the meeting is to offer a concentrated post-graduate course in recent advances in clinical medicine and surgery as interpreted by eminent clinicians who will be guest speakers. Over sixty such guest speakers have already honored the society in the past. This year's speakers offer an especially attractive series of clinical lectures.

Aware of the ever increasing importance of more recent social trends as they affect organized medicine, the committee has secured Dr. Morris Fishbein, who will deliver an address to which the general public will be invited. Two luncheons and banquets will be reserved for relaxation and entertainment.

Among those taking part in the program are the following:

Dr. Gershom J. Thompson: "Transurethral Prostatic Resection."
Dr. Q. U. Newell: "Cancer of the Uterus."
Dr. Fred J. Taussig: (Round Table Discussion) "Treatment of Septic Abortion."
Dr. F. J. Taussig: "The Coördination of Radium with Surgery in the Treatment of Cervix Cancer."
Dr. Willis C. Campbell: "Some Aspects of Surgery of the Hip Joint."
Dr. Heyworth N. Sanford: "Jaundice in the New Born."
Dr. Heyworth N. Sanford: (Banquet) "Some Observations on Disturbances of Blood Coagulation."
Dr. August A. Werner: "The Effect of the Ductless Glands in Growth and Development."
Dr. Ralph A. Kinsella: "The Pneumonias."
Dr. Walter C. Alvarez: "Useful Hints in the Treatment of Indigestion."
Dr. Maurice C. Howard: "Problems of Gastric Hemorrhage."
Dr. Morris Fishbein: (Noon Luncheon) "American Medicine and the National Health Program."
Dr. Morris Fishbein: (Open Public Address) "The Social Aspects of Medical Care."
Dr. J. A. Myers: "Modern Methods in Diagnosis and Therapy of Tuberculosis."
Dr. Coyne H. Campbell: "Practical Points in the Management of Neurotic Symptoms, Inhibitions and Anxiety."
Dr. Manuel Grodinsky: "Pyogenic Infections of the Hand and Foot."

The St. Joseph Clinical Society extends a cordial invitation to all members of the medical profession who may wish to be guests at this clinical gathering.

WOMAN'S AUXILIARY

Mrs. W. B. Roberts, Minneapolis, *President*
Mrs. E. V. Goltz, 2259 Summit Avenue, Saint Paul, *Publicity Chairman*

The Women's Auxiliary of the Olmsted-Houston-Fillmore-Dodge County Medical Society met at 8 P. M. January 4, at the Mayo Foundation House, Rochester. Edward H. Weld, Jr., described health insurance plans being tried in various localities. About twenty-five members were present. Following the talk by Mr. Weld, Mrs. H. C. Habein, president, showed colored motion pictures of England which she had taken on her recent trip abroad. Refreshments and a social hour followed.

* * *

Mrs. M. L. Hershfield of Duluth, state parliamentarian, was a guest of Mrs. Wm. B. Roberts, state president, in Minneapolis, January 6 and 7.

* * *

Mrs. A. A. Passer, member of the Advisory Committee, was a guest in the Twin Cities, January 9 and 10.

* * *

The second State board meeting will be held in Saint Paul, Wednesday, February 1. Mrs. E. M. Hammes of Saint Paul is the social chairman for the event and Dr. George A. Earl will address the group. Mr. F. M. Brist will be the guest speaker.

* * *

The Women's Auxiliary of the Ramsey County Medical Society announce that they cleared $1,500 from the play "The Dream of a Clown" which they sponsored December 16 and 17, in the Saint Paul Auditorium. Much credit is due those members who contributed their energy and time for the success of this undertaking.

The Ramsey County Auxiliary will present cups to the two winners of essays which were chosen during the recent tuberculosis campaign at the regular meeting of the group, January 23. The winners who will read their essays for the organization are Eileen O'Keefe, a pupil of the Visitation Convent, and Clinton Marshall, a pupil of John Marshall High School. The title of the essays is "Tracking Down the Foe of Youth—Tuberculosis."

The Red Cross Society has announced that the Ramsey County Medical Auxiliary led all other organizations in the selling of Red Cross subscriptions—based on the percentage of the amount over the quota given to sell. Mrs. J. A. Moga, assisted by her committee, made 133 per cent over their quota in the booths in the Lowry Medical Arts Building.

PROCEEDINGS OF THE MINNESOTA ACADEMY OF MEDICINE

Meeting of November 9, 1938

The regular monthly meeting of the Minnesota Academy of Medicine was held at the Town and Country Club on Wednesday evening, November 9, 1938. Dinner was served at 7 o'clock and the meeting was called to order at 8:10 p. m., by the President, Dr. R. T. La Vake.

There were sixty members and one guest present. Minutes of the October meeting were read and approved.

The proposed amendment to Article III, Section 1, of the Constitution, making possible an increase in University Membership from five to ten members, was voted on and carried.

The scientific program consisted of five case reports as follows:

ACUTE FATAL CORONARY THROMBOSIS WITH GALLBLADDER SYMPTOMS

Report of Case

Charles N. Hensel, M.D.
Saint Paul

Mrs. C. R. C., aged fifty-five; former occupation, nurse; married eight years; childless; entered Miller Hospital, Saint Paul, February 10, 1938, and died on February 22, 1938.

On entering the hospital her chief complaints were heartburn, intense pain in upper right quadrant, nausea and vomiting.

She had had polyarthritis at the age of thirty-four followed by mitral valvulitis and stenosis, with recovery. She was a nurse in the Veterans' Bureau from 1921 to 1930. Appendectomy in 1924. No history of gallbladder disease. She was in Miller hospital in 1932 for three months with congestive heart failure following coronary occlusion, making a good recovery. Blood pressure varied from 170/100 to 135/85. Radiograph of the heart at that time showed a universal enlargement, particularly to the right, prominence of pulmonary conus, bulging of left auricle into the mediastinum as disclosed by barium meal in gullet. Total transverse diameter was 15.2 cm.—52 per cent of chest diameter. The patient was fairly active after leaving the hospital, with occasional attacks of auricular fibrillation and mild congestive heart failure relieved by bed rest and cardiac tonics.

History preceding present recent admission to the hospital: On January 28, 1938, she was seen at the office because she was greatly agitated over the recent death of two dear friends and the possibility that she might be involved in litigation of the will of one of them in which she was a beneficiary. Blood pressure at that time was 184/90, heart rate 72, rhythm regular, presystolic murmur at apex and a snapping pulmonic second.

On February 7, 1938, she was seen at home complaining of intense heartburn for the past seven days. This was described as a pressure pain or a burning sensation at the tip of the sternum at the right costosternal margin. The heart showed no changes in rate, force or rhythm. Blood pressure, 156/98. Lungs clear. Abdomen soft and pliable. No tenderness in the region of the gallbladder. Temperature was normal. Her condition was considered not serious. Antacids and antispasmodics were prescribed. Two days later (February 9) the patient 'phoned that she felt relieved and would go through with a dinner party that evening as planned.

The following day (February 10) she was seen at home propped up in bed, rocking back and forth in great distress, still complaining of burning pain at the tip of the sternum and along the right costal margin. She had vomited all night long. On examination, the lungs were negative, heart showed no abnormalities in rate, force or rhythm. The gallbladder region gave some tenderness and some muscle spasm on examination. She was sent into the hospital for studies of the gallbladder. The heart was not considered to be the source of symptoms.

Radiographs of the gallbladder showed a large, flaccid gallbladder, tortuous in outline, good density but sluggish in emptying; no stone shadows. Sedimentation rate—1 hour, 52. Urine showed a trace of albumin and no sugar. Hb. 76 per cent, r.b.c. 4,220,000, w.b.c. 12,100.

On February 12, Dr. Zimmermann saw the patient in consultation—the condition not considered surgical, might be due to heart. The patient was fibrillating at the time of examination. She was still complaining of epigastric pain, nervous and very emotional.

On February 14, her condition became critical, pulse imperceptible, blood pressure 82/64, electrocardiograph, auricular flutter 2-1. In an oxygen tent there was sudden collapse, convulsive movements, and the patient became unconscious. Death was imminent. The patient became cold all over, occasional gasping, heart tones feeble, rhythm regular, rate 100. After about three-quarters of an hour in this condition the patient began to breathe normally, opened her eyes, and remarked, "I think that I have died; I cannot see; I cannot move my arm." She had a flaccid paralysis of the right arm and was blind although examination of the eye grounds was impossible due to contraction of the pupils.

From February 15 to February 22, 1938, the patient was unable to retain nourishment by mouth, in a state of marked mental agony asking to die, asking for relief, asking for opiates (which were given freely without calming effect). The patient thrashed and threw herself about, became increasingly dyspneic and cyanotic, heart rate rapid, rhythm irregular, tones feeble, pulse barely perceptible. Blood pressure 76/60. First elevation of temperature on February 16 at 99°, rose to 101° at death. Leukocytes 24,000 to 34,000. As her heart failed, the urine showed increasing amounts of albumin and hyalin and granular casts. On February 17 the blood sugar was 111 mgm. Coma developed on February 20. The patient expired on February 22 and an autopsy was obtained.

Autopsy.—Chief findings in heart: Weight 450 grams. The epicardium is rough and covered with flakes of fibrin. The pericardial sac contains about 15 c.c. of thick, purulent fluid. The myocardium is dark red in color, fairly firm in consistency. The left ventricle is 1.5 cm. thick. Along the course of the anterior descending branch of the left coronary are seen numerous white patches of fibrosis in the heart muscle. Along the posterior branch of the left coronary are seen grayish green areas of infarction extending into the interventricular septum. The endocardium is smooth and free from thrombi. The mitral valve is thickened and fibrous. A fairly firm vegetation about 5 mm. in diameter is found at the periphery of the valve. The remaining valves are normal. The root of the aorta shows a smooth intima. The coronary arteries are markedly sclerotic throughout. The lumen of the left coronary is considerably narrowed. Two centimeters from the orifice of the left coronary artery the lumen is practically occluded by a thickening of the wall and a fairly soft coagulum which was probably terminal.

Findings in the gallbladder were normal.

Comment.—This is a case of diffuse coronary sclerosis with an area of fibrosis from a healed infarct (1932). Progressive occlusion of the smaller branches of the posterior portion of the left coronary artery resulting in a patchy infarction, all recent, *i.e.,* from a few days to within three weeks, undoubtedly accounting for the burning pain in the epigastrium. Examination of the head was not permitted, but the finding of a fresh vegetation in the mitral valve explains the convulsive attack, blindness, paralysis of the right arm occurring a week before death.

LACERATIONS OF LARGE AND SMALL INTESTINE WITHOUT PERFORATION

Report of Case

A. W. Ide, M.D.

Saint Paul

This patient is a young man, eighteen years old. He was employed as a machinist apprentice in a railroad shop and was injured October 8, 1938, at 9 o'clock in the morning.

In the shops, where he was working, a locomotive drive wheel was being moved by means of a power hoist. This wheel was resting on the floor of the shops but held in a nearly upright position by means of chains attached to this hoist. The wheel was not directly upright but was leaning slightly to one side. In the course of the work, the position of the wheel was changed and it was tipped toward the other side. As the wheel tipped, it struck this patient in the lower abdomen. The wheel had nearly reached its permanent position before the blow was struck so that the blow was not apparently very severe. It was, however, sufficient to immediately cause the patient very severe pain in the lower abdomen. He was immediately brought to the hospital in an ambulance.

On examination, the patient appeared to be a normal young man in very acute pain. The abdominal muscles were relaxed except on the left side, where there was a moderate degree of rigidity. There was great pain in the lower abdomen on the left side and near the iliac crest. The patient's general appearance and complaint gave one the impression that he had sustained a severe bone injury in this region. There was some vomiting. He was given a hypodermic injection of a quarter grain of morphin sulphate on admission and another sixth of a grain of the same drug two hours later. The morphin relieved the pain somewhat but the patient did not sleep. He still complained bitterly of pain and localized this pain in the region of the lower abdomen.

A catheterized specimen of urine showed no blood or other abnormality. A blood examination showed 85 per cent hemoglobin, with 4,270,000 red blood cells and 8,900 white blood cells. The temperature was normal. The pulse rate on admission was 86.

About three hours after the injury he began to develop rigidity of the abdominal muscles and at 3 p. m., six hours after the injury, the abdomen was boardlike. A diagnosis of perforation of the bowel was made and operation was advised.

A left rectus incision was made. There had been some bleeding in the abdominal cavity but it was not at all extensive. Lacerations of the bowel were found as illustrated (Fig. 1). There was one laceration in the lower sigmoid, 3 inches in length and 1.5 inches in width. The outer coats of the bowel were torn but the mucous membrane was still intact. There was another laceration just below the splenic flexure. This was 2 inches in length and 1 inch in width. There was another laceration about midway in the transverse colon and there was a similar laceration of the small bowel. The lacerations were repaired. There was no sign of bowel content in the peritoneal cavity and no actual perforation could be found in the regions of laceration. General exploration of the abdominal cavity was made but no further injury could be found.

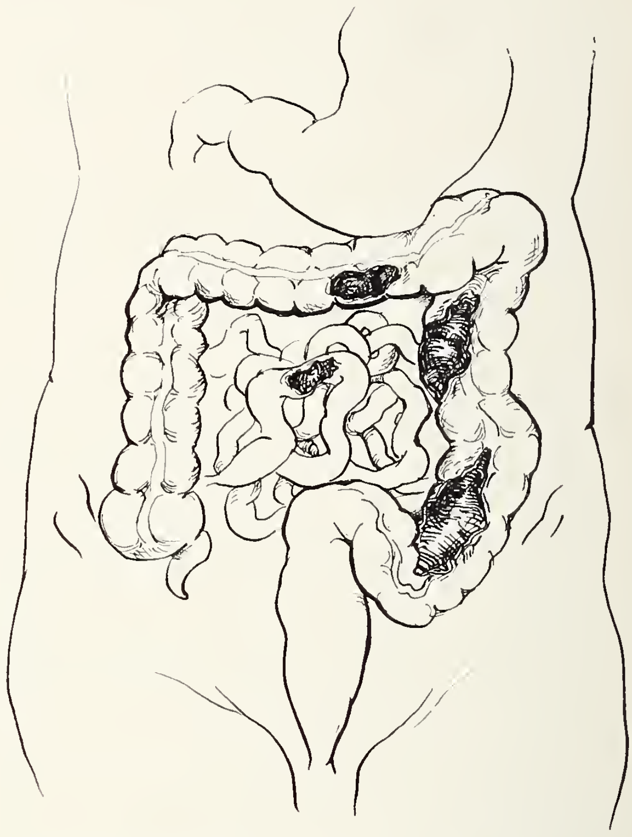

Fig. 1. Lacerations of the large and small intestines without perforation.

The abdomen was closed without drainage and the patient has made an uninterrupted recovery.

Comment.—This case was interesting to us primarily because of the fact that the patient developed signs of perforation of the bowel when no actual perforation was present. The lesions consisted of multiple lacerations of the bowel without perforation. There were no injuries to the other abdominal organs and there were no injuries to any bones.

CONGENITAL UNILATERAL RENAL AGENESIA

Report of Case

Martin Nordland, M.D.
Minneapolis

The case is that of a female patient, sixty-four years of age, married, who, on December 2, 1937, was taken ill with a pain in the upper abdomen. She stated that it came on shortly after she ate her Sunday dinner. The pain lasted during that day and the following night but was not sufficient to keep her awake. She was not nauseated. She had two stools before retiring, which was unusual. For the next two days she was fairly well relieved with a hot water bottle. Although she was not very ill, she called a physician on the third day because the pain, which had localized in the right lower abdominal quadrant, had not entirely subsided. She entered the hospital with a diagnosis of appendicitis.

On admission her temperature was normal, pulse was 90, and hemoglobin 93 and 95 per cent, N & D. The leukocyte count was 49,900, which was checked. Red cells numbered 5,060,000. The differential whites were: small lymphocytes, 5.5; large monocytes, 11.5; and polymorphonuclears 80 per cent.

The urine was reported to have an orange color, cloudy appearance, acid reaction and specific gravity 1.033. There was a large trace of albumin and no sugar. There were no casts and the microscopic field was obscured by bacteria. On the following day the color of the urine changed to straw, it was clear, still had a large trace of albumin, no casts and the microscopic examination showed 6 to 10 pus cells per high-power field and 1 to 4 red blood cells. The third specimen, on the succeeding day, showed urine straw colored and clear, still a large trace of albumin, no casts and 100 to 150 pus cells per high-power field and 60 to 80 blood cells.

The leukocyte count in the three days after admission dropped from 49,900 to 40,000, 28,000 and 18,400.

The patient was a rather slender individual, moderately well nourished, and during the four days following her admission the physical examination was essentially negative except for the presence of a firm mass which seemed to fill the right abdomen down to the level of the right anterior superior spine. There was no rigidity but there was a slight spasticity of the right rectus muscle. The mass seemed a little irregular and was only a little tender. There was considerable pain over the right kidney region, posteriorly. On account of the "orange" color of the first specimen of urine examined, the urinalysis referred to above and the high leukocyte count, together with the pain in the region of the right kidney, a tentative diagnosis of surgical lesion of this kidney was made.

Plates were made of the urinary tract and the roentgenologist's report was as follows:

> "These show the outline of the left kidney clear. This is not enlarged. The outline of the right kidney and *right psoas shadow is obscured.* There is no evidence of urinary stone. Plates made after the injection of diodrast show the pelvis and calyces of the left kidney and left ureter to be well outlined. There is no excretion of the dye from the right side.
>
> "Conclusions: The right kidney outline is not visualized. The *right psoas muscle is not visualized.*
>
> "Following the dye, we can demonstrate the kidney and ureter on the left side. No conclusions can be drawn from the right side except that the right kidney is not functioning at this time."

Two days later a cystoscope was introduced and exploration of the bladder revealed the absence of a right ureteral orifice. The left ureteral orifice was observed, slightly prolapsed. The bladder was otherwise normal. Spurts of clear urine came at regular intervals, about every five seconds, from the left ureteral orifice. Indigo carmine was introduced intravenously. Function was normal on the left but nothing appeared on the right and further search revealed complete absence of the right orifice.

Ten days after admission, the patient was comfortable, without temperature, leukocyte count 14,500 and the urine, which was clear and straw colored, showed only a trace of albumin with only 5 to 10 pus cells and no red blood cells per high-power field. The mass described was still present.

Preoperatively, it was felt that the mass could be reached best through the abdomen anteriorly, but, because of the possible presence of pus, we felt that it was best to approach it through an extraperitoneal kidney incision. Exploration revealed no evidence of the kidney or a congenital residue. The peritoneum was opened and we found we were dealing with a huge gallbladder. The liver border was at the level of the iliac crest and the fundus of the large gallbladder (7 inches in length) extended into the pelvis. Adhesions of recent origin were present between the gallbladder and the parietal peritoneum over the ileopsoas muscle. A portion of the duodenum and the cecum were attached to the anterior surface of the gallbladder. There was a large amount of exudate on the parietal peritoneum adjacent to the attachment of the gallbladder. The gallbladder, which was tense, markedly thickened and which contained numerous stones of various sizes, was easily removed through the excellent exposure of this incision.

The case was thought to be of interest because of the difficulty of the preoperative diagnosis, because of the congenital absence of the right kidney, and because of the ease with which this large gallbladder could be removed through the unusual approach of a kidney incision.

Collins, in a discussion of congenital unilateral renal agenesia in 1931, stated that review of the literature revealed 572 cases. At that time nine additional cases were added from the Section on Pathologic Anatomy of the Clinic. Braasch stated that congenital absence of the kidney was probably not of great clinical significance but that a clinical diagnosis of agenesia would be impossible. Only the circumstances as existed in this case or a postmortem examination would ascertain this condition. He further stated that the value of Dr. Collins' data, other than being a contribution to renal pathology, lay in the fact that it emphasized the occurrence of solitary kidney.

Discussion

Dr. W. F. Braasch, Rochester: The clinical recognition of renal agenesia is not as rare now as it used to be. Since the advent of excretory urography, solitary kidneys are discovered rather often. Just because only one kidney is visualized in the excretory urogram, however, does not necessarily infer that the other kidney is absent because of agenesia. It must first be proved that the absence of renal function is not temporary and the result of a remediable cause. If the kidney is absent, one must determine whether the condition is congenital or acquired. The diagnosis of congenital absence of the kidney, or renal agenesia, can be made from the original roentgenograms because of several data. The outline of the congenital single kidney is much larger than that of the acquired single kidney and its position is much lower. Finding the kidney shadow on one side only, especially if the renal shadow is very large and is situated very low, would, in most instances, be very suggestive of renal agenesia.

The absence or dimming of the psoas shadow on the side of the absent kidney, with accentuation of the psoas on the other side, is often observed in the roentgenogram. I don't know why the psoas shadow should be diminished. I asked Dr. Scammon for information about this, but he was unable to give me any. Possibly it is caused by a failure of development of renal innervation and branches supplying the psoas muscle. Sometimes the psoas shadow on the side of the absent kidney is very broad and well developed. Corroborative evidence of agenesia is often derived from the cystoscopic examination. The interureteral ridge on the side of the absent kidney is usually undeveloped and the ureteral orifice is absent. Having the data available from the original roentgenogram and from the excretory urogram, if the psoas shadow on the side of the absent kidney is faintly visible and accentuated on the other side, one should be able to recognize renal agenesia in most cases.

Dr. F. E. B. Foley, Saint Paul: The title of this case report, "Renal Agenesia," is a misnomer. Obviously the gallbladder condition was the important thing with the renal anomaly merely an incident. This, however, does not detract from the interest of the latter. The condition was important in the diagnosis in this case and particularly so in being misleading.

Renal agenesia or congenital absence of the kidney not infrequently comes up for consideration in diagnosis. The condition exists in two forms. In one the congenital defect is primarily in the renal blastema. In that case a ureteral bud forms from the Wolffian duct and develops into a normal ureteral orifice and ureter of some length. Because of aplasia or absence of the renal blastema the kidney proper does not develop and the ureter ends blindly. In this event there is congenital absence of the kidney combined with a normally formed trigone, presence of both ureteral ridges, both ureteral orifices and on one side a ureter of some length ending blindly. In the second form of the condition of which this case is an example the congenital defect is primarily in the Wolffian duct. It fails to form a ureteral bud and no ureter develops. Even if the blastema is present it receives no ureteral bud and in consequence does not develop a kidney. In this form of the anomaly one side of the trigone, the ureteral ridge, orifice and ureter and kidney are all absent.

CHRONIC CONSTRICTIVE PERICARDITIS WITH CALCIFICATION

Report of Case

Moses Barron, M.D.

Minneapolis

The case I am presenting this evening is one that was sent to me with the diagnosis of heart disease. The patient had been treated for this condition for several years and had become bedridden during the previous six months. This type of case presents all the symptoms and findings of congestive heart failure but may also be confused with cirrhosis of the liver. An exact diagnosis was absolutely essential for the proper management of this case, since she did not respond to the usual medical management and required surgical interference, before any improvement was obtained.

A woman, aged forty-five, married, was first seen on August 15, 1938. She came in complaining of swelling of the abdomen of two years' duration, weakness of one year's duration, loss of weight, inconstant edema of the legs, and with symptoms so severe that she had been confined to her bed for six months.

Past history: In 1925, at the age of thirty-two, she had scarlet fever. During convalescence she developed acute rheumatic fever which laid her up for two months. She thinks that at that time her heart became involved. Following this she felt tired and noticed dyspnea on exertion. About a year later she was in an auto accident when her chest was crushed. She was taken to a hospital where she was told she developed pus around her heart, that is, a suppurative pericarditis. She stayed in the hospital only five days, when she was sent home. Her recovery was slow. Finally, she felt quite well again. She performed her usual duties until about two years ago, when she noticed progressive weakness and enlargement of the abdomen. Later she noticed her ankles would swell while she was up and around. She developed a peculiar pressure sensation in the chest which, together with the shortness of breath, made it difficult for her to talk at times. The abdomen began to swell and became so large that, in February, 1938, paracentesis was performed, when eight quarts of clear fluid was removed. This was repeated in June and an equal amount of fluid was withdrawn. She had been confined to her bed since the first paracentesis. During the past year she was given salyrgan and digitalis with very little if any relief. She had to be careful with her diet because many foods produced gas, belching and bloating. She had had a number of attacks of pain in the right upper quadrant which was diagnosed gallbladder disease about ten years ago. She has been free from these attacks lately.

Physical examination: The patient was 5 feet 3 inches tall, weighed 124 pounds, pulse 74, blood pressure 110/80. There was a slight edema of the lower back. The heart was apparently not enlarged, tones faint and impure, the pulse small and irregular, the heart was fibrillating. There were pulsations in the vessels of the neck, more on the right. The lungs were clear. The abdomen was large and presented all the evidence for the presence of a large amount of free fluid. The liver came down about 5 cm. below the costal margin, the edge was firm. Pelvic examination was negative. The blood showed Hb. 80 per cent, 8,600 leukocytes, with normal differential; Wassermanns were negative. The urine was negative. An electrocardiogram showed low voltage in all the leads, T_1 isoelectric, T_2 and T_3 slightly negative. There was slight slurring of the QRS in the second and third leads. Tracings were taken in three positions: with the patient on the back, on the right side and on the left side. All the tracings appeared alike, with practically no change in the different positions and presumably no shifting in the cardiac axis. A 6-foot heart radiograph showed the heart in midposition with marked calcification of the pericardium. It appeared as if the heart were enclosed in a calcium shell. The lateral film showed this even better than the antero-posterior view. Venous pressure showed a definite increase to 20 to 25 cm. of water in the antecubital vein (normal 5 to 8 cm.). There was a florid cyanosis. The diagnosis was constrictive pericarditis with advanced calcification.

Comment.—This patient presents very important findings for diagnosis. The ascites and the enlarged liver may suggest cirrhosis of the liver. However, there is a negative history of alcoholism and there was a marked dyspnea on the slightest exertion which is not common in cirrhosis. The increased venous pressure was definitely against such a diagnosis, if uncomplicated, as was also the electrocardiogram. The x-ray findings helped to rule out cirrhosis of the liver and establish the true diagnosis. The question of congestive heart failure came up for consideration but the marked increase in venous pressure in spite of the absence of cardiac enlargement pointed strongly against it. Such a combination is extremely rare in congestive heart failure. Another finding against such a diagnosis is the absence of evidence of pulmonary congestion in the presence of marked dyspnea on the slightest exertion.

In résumé, then, the essential findings for the diagnosis of constrictive pericarditis in this case were the increased venous pressure without cardiac enlargement, enlargement of the liver with marked ascites, dyspnea without evidence of congestion of the lungs, marked weakness, diminished apical impulse, low pulse pressure, fixation of the heart as found by physical examination as well as by fluoroscopy and electrocardiogram, and the finding of calcification of the pericardium. The condition may be described as "inflow stasis." An insufficient amount of blood is able to enter the heart chambers, which results in a diminished output. A similar condition is often brought about mechanically by severe tricuspid stenosis. In these cases the x-ray examination is exceedingly important. Fluoroscopic evidence of the absence of pulsations at the cardiac borders is very characteristic. In the present case the x-ray examination showed, in addition, the extensive calcification of the pericardium.

Treatment.—Medical management offers very little lasting relief in these cases. In only a few cases, where there may be some associated congestive heart failure, does digitalis prove of value. The only procedure which holds out promise for extensive relief in the majority of cases, and perhaps a practical cure in about one-third of the cases, is surgical interference. Decortication has proved to be life-saving in a large series of cases reported by many authors. The present case was referred to Dr. Owen Wangensteen of the University for surgical treatment. On August 23, 1938, Dr. Wangensteen operated under intratracheal anesthesia. The postoperative course was satisfactory and the patient was discharged from the hospital on September 10. She returned for a checkup the latter part of October. At this examination she was able to be up and around, with very little dyspnea. The ascites had completely disappeared so that the abdomen was flat. The patient said that she now feels well except for some weakness. However, the venous pressure is still above the normal. The x-ray now shows that the heart has now enlarged to the left, and that the left border has fair excursion. It is very likely that a secondary operation may have to be performed to relieve the right auricle and ventricle, which could not be done at the first operation. The improvement up to now has been most striking. Dr. Wangensteen will discuss the surgical phase of this type of case.

Discussion

Dr. O. H. Wangensteen, Minneapolis: I am grateful to Dr. Barron for the privilege of participating in the care of the patient whose condition he has discussed. He recognized the nature of the disorder. The disturbance having been identified, determination of the proper therapy was but a natural sequence.

Before discussing the surgical aspects of constrictive pericarditis, I should like to emphasize the physical criteria mentioned by Dr. Barron by which the disorder may be recognized. A high venous pressure as indicated by prominence of the jugular and antibrachial veins at heart level and a low arterial pressure and a small pulse characterize the condition. The apex beat may not be felt with the hand and fluoroscopically the limited motion of the heart is striking. The heart may appear small on a roentgenogram, but fluoroscopic visualization is more revealing. If saline solution is allowed to run from a glass tube into an arm vein with the arm at the level of the right atrium, the height at which the column of fluid comes to a standstill determines the venous pressure. These findings are the same whether tamponade of the heart is occasioned by blood, fluid or pus in the pericardial sac or by a thickening of the pericardium limiting and restraining the motion of the heart.

In 1898 the French surgeon Delorme[1] suggested that an operation might be done for constrictive pericarditis in which the thickened pericardium is divided and stripped from the heart muscle. He did not then do the operation, however. In 1902 Brauer[2,3] suggested that the ribs and cartilages overlying the heart be removed in those instances of constrictive pericarditis in which there was retraction of the chest wall in cardiac systole. Only those patients in whom adhesive bands from the pericardium attach to the anterior chest wall causing a tug on the chest wall during systole of the heart would be helped by such a procedure. In instances which meet the operative indication it probably would be well to take measures to preclude reformation of bone from the periosteal rib beds and the perichondrium. It is quite obvious, however, that the Brauer operation would be of no avail in the presence of constrictive pericarditis. The younger Rehn[4,5] was the first to do the operation suggested by Delorme some years before. It was, however, the conjoint effort of the internist Volhard and the surgeon Schmieden which established the practicability of the Delorme operation in the relief of constrictive pericarditis.[6]

I believe I am correct in saying that Churchill of Boston was the first in this country to operate successfully for the relief of this condition and that as recently as 1929.[7] The success with which Churchill has dealt surgically with the condition of bronchiectasis, establishes him as one of the keenest exponents of thoracic surgery in the world. He has reported recently[8] a group of eighty-four cases of bronchiectasis for which he did lobectomy with a mortality rate of 4.7 per cent. There was only one death in the last sixty-six cases—a really remarkable achievement when one appreciates the potentially formidable character of the operation.

In the aggregate, there must now be on record somewhere in the neighborhood of a hundred cases of constrictive pericarditis which have been treated successfully by operation. Schmieden's series has grown to twenty-two in number.[9] In this country Beck at Cleveland,[10] Churchill at Massachusetts General Hospital,[11] Blalock at Vanderbilt,[12] and Heuer at Cornell,[13] have each had a unique surgical experience with the condition. Harrington reports a successful instance in the current issue of the Mayo Clinic bulletin.[14]

As Schmieden has pointed out[15] the decortication should begin over the left ventricle. The right ventricle, of course, after opening the chest wall through a left para-sternal incision comes into view most quickly. If it be decorticated first the inflow stasis of peripheral vascular inadequacy to which the patient has in part accommodated himself may then be replaced by pulmonary edema—a tragic occurrence which Schmieden encountered in one of his early cases. Preliminary decortication of the left ventricle will permit it to deal with the restraint to "inflow stasis" which will accompany decortication of the right ventricle.

Both Schmieden and Churchill warn that attempts should not be made to remove scar from the thin atrial walls. The dissection must stop in the auriculo-ventricular grooves. Care, however, must be observed to see that the heart is loosened from the diaphragm inferiorly.

In the instance of Mrs. E. J., aged forty-five years, University Hospital No. 671539, reported by Dr. Barron, the pericardium was calcified and the heart encased in a stony, hard mould. The pericardium could not be cut with scissors or knife, but had to be trimmed away with bone shears. I decorticated the entire left ventricle and the anterior portion of the right. It is important to adapt the operation to the patient and not do too much at one sitting. It is noteworhy nevertheless that Schmieden completed all but one of his twenty-two operations in one stage. As Dr. Barron indicated, this patient has improved astonishingly. She left the hospital somewhat less than three weeks after the operation without evidence of edema or ascites and is still edema and ascites free. There is some slight residual evidence of fluid in the left pleural space, but this, I believe, is incident to the opening of the pleura at operation. Despite the fact that this patient appears clinically well, the presence of an elevated venous pressure (still 20 cms. of saline solution) indicates that it probably would be wise to remove the calcified pericardium from the entire right ventricle.

A prior experience with another patient suggests this also. Two years ago I removed the greater portion of the constricting pericardium from Mr. C. R., aged forty-two years, University Hospital No. 650540. He improved slowly, and the consideration of another operative procedure carried out through an incision in the right thorax was debated. Because of the technical difficulties of establishing the plane of cleavage between the thick pericardium, in the lamination of which encysted fluid had accumulated, and the epicardium, subsequent operation was deferred and the patient dismissed from the hospital. Three months later when he returned his condition was such that reoperation was out of the question.*

Constrictive pericarditis is a disorder which should be recognized readily. It is by no means a common condition. Surgery in suitable cases offers a direct and dramatic means of terminating heart failure and invalidism.

Dr. W. H. Condit, Minneapolis: What takes the place of the pericardium?

Dr. Wangensteen: A number of persons, Doctors Fahr, Sperling and myself among others,[16] have removed the entire pericardium in dogs and observed that the capacity of such dogs for work on the treadmill was equal to that of normal animals. Useful as the pericardium may be in preventing acute cardiac dilatation, it is not an indispensable membrane, for dogs seem to get on quite well without it.

Dr. F. R. Wright, Minneapolis: Has the patient gained anything? What has been accomplished by it?

Dr. Barron: The records from the literature show that 50 per cent of the cases are practically cured, even though not able to do any hard work. This patient is able to work around the house as long as she doesn't hurry. It has been about eight weeks since operation. If you could see that patient and see how comfortable she is, one would think the operation is worth while. There is still some constriction around the large vessels.

*Since presentation of this paper a third patient with constrictive pericarditis has been operated upon (L. G., aged eleven years, University Hospital No. 639977). Diuresis following pericardiectomy was striking. The operation was performed November 25, 1938, and the patient is still in hospital convalescing.

PRIMARY CARCINOMA OF THE URETER

F. E. B. Foley, M.D.
Saint Paul

The case to be reported is of unusual interest because of the rarity of the condition it presents, the classical clinical features it showed including particularly a deformity in the pyelo-ureterogram characteristic of the condition and because of the particular form of operation employed. For the sake of brevity only essential details will be set forth.

A spinster, sixty-nine years old, was referred to me by Dr. Lepak on June 15, 1938, because of blood in the urine. Two weeks before Dr. Lepak referred her to me she had consulted him because of dizziness. Two days later she noted that the urine was colored with blood. Hematuria had never occurred before and she attributed it to drugs prescribed by Dr. Lepak. Hematuria was present with every urination from noon until going to bed at night. Following this there was no recurrence of gross hematuria. Dr. Lepak reported that the drugs prescribed could not be responsible for the hematuria. Dr. Lepak examined specimens of urine on several subsequent days. He found none of them grossly colored with blood but found in all of them a considerable number of red blood cells on microscopic examination.

On close inquiry in regard to pain suggestive of renal origin there was an account of a fall and striking the lower ribs on the right side followed by periods of slight pain and tenderness in this region ever since. The description of the pain, its character and location were not strongly suggestive of upper urinary tract origin.

There was no reaction to Murphy percussion on either side, there was no tenderness to deep bimanual pressure in either flank and neither kidney was palpable. No mass or tenderness could be made out in the abdomen. Well up in the vaginal vault on the right side lying close to the bladder wall and extending over to the pelvic wall, very definite induration and firmness could be felt. Apart from this the findings of the physical examination were negative. The urine was clear and the findings of the urine examination were all normal except for the presence of six red blood cells per high power field in the centrifuged specimen. The urinary tract radiograph gives a good outline of each kidney, the left being of normal size, configuration and position while the right is of decidedly smaller than normal size and rather low-lying. There is a small irregular shadow overlying the right margin of the sacrum remotely suggestive of ureteral stone.

The cystoscopic examination disclosed a perfectly normal bladder interior. A ureteral catheter ascended the left ureter against no abnormal resistance while on the right side an F6 ureteral catheter encountered strong resistance beginning 4 cm. above the orifice. Only by splinting the catheter with a wire stilet in its lumen could it be further advanced. Using some little force it ascended to the renal pelvis. Only 1 or 2 c.c.

of urine could be aspirated from the catheter in the left ureter while aspiration of the catheter in the right ureter obtained 30 c.c. of urine. Indigo-carmine given intravenously appeared promptly in good concentration in the urine dripping from the left catheter. At the end of 10 minutes the dye had not appeared in the urine dripping from the right catheter.

The bilateral pyelo-ureterogram is shown here. The calyces, pelvis and ureter on the left side are all quite normal. On the right side there is a grade 2 dilatation of the pelvis and calyces with the pelvis of rounded bulging type. The bulging pelvis overlies the uretero-pelvic junction, which is not visualized and leaves unanswered the question of uretero-pelvic junction obstruction. The ureter is dilated grade 2 from the kidney down to a point 6 or 8 cm. above the bladder. From here down to the bladder there is an irregular distribution of the contrast medium in the form of irregular tangled streaks not outlining definitely a ureteral lumen. The deformity is strongly suggestive of ureteral neoplasm with the ureteral lumen occupied by irregular soft papillary growth. The small irregular shadow overlying the right margin of the sacrum is outside the ureter and the possibility of it representing a ureteral stone is definitely excluded.

For consideration in diagnosis the salient features were:

1. The history of gross hematuria.
2. Long continued presence of red blood cells in the urine after cessation of gross hematuria.
3. The history of occasional pain or discomfort in the right flank.
4. The palpable induration in position of the pelvic portion of the right ureter.
5. The impaired function of the right kidney.
6. The dilatation of the right pelvis and ureter.
7. The typical deformity in the outline and filling defect of the ureter shown in the pyelo-ureterogram.

The features enumerated warranted the positive diagnosis of "ureteral neoplasm—probably primary."

Operation was performed July 6, 1938. Because of the patient's stature and the low position of the right kidney it was possible to make the "nephro-uretero-partial cystectomy" through a single incision instead of through a flank incision and second incision in the lower abdomen as usualy employed. The incision was started below the tip of the twelfth rib and extended obliquely forward and downward in the lower quadrant to the midline a little above the level of the pubes. This gave adequate room to satisfactorily expose the kidney, whole length of ureter and adjacent bladder wall. The whole procedure was extra-peritoneal. An elliptical section of bladder wall measuring about 2 x 4 cm. with the attachment of ureter and ureteral orifice at its center was removed.

The postoperative course was uneventful.

The removed kidney, ureter and section of adjacent bladder wall are here for your inspection. Lantern slides of photomicrographs show the histologic appearance of the growth. It is a primary carcinoma of the ureter.

The first description of a case of ureteral tumor was by Rayer in 1841 but was not verified by histologic examination. In 1916 only seventeen cases of the condition had been reported. In 1934 the number had increased to only sixty-one verified cases. Two years later the total number of cases verified by histologic proof was ninety-six, indicating, of course, an increase of interest in the condition rather than any actual increase in the frequency of its occurrence.

How frequently primary neoplasm of the ureter occurs is impossible to say. Among 22,000 autopsy protocols of the Bellevue Hospital from 1904 to 1935 only one case of primary carcinoma of the ureter is noted. Among 22,181 patients in the Brady Urological Institute of Johns Hopkins Hospital there were only three cases of the condition. From these observations and from the scarcity of reported cases in the literature it is obvious that the condition is remarkably infrequent.

The symptoms of tumor of the ureter are quite variable. The classical triad of hematuria, pain and tumor mass are present in only a small proportion of the cases. The symptom most frequently prompting medical care is hematuria. The growth obstructs the ureter and usually produces some degree of hydroureter and hydronephrosis with accompanying pain. If the tumor is located in the upper two-thirds of the ureter, it will not be palpable until of considerable size. When located in the terminal portion of the ureter, it may, as in this case, be palpable relatively early.

Before the advent of pyelography the condition was recognized prior to operation in only about one-fifth of the cases.

Discussion

Dr. W. F. Braasch, Rochester: Dr. Foley is to be congratulated on making the clinical diagnosis in the case of primary tumor of the ureter that he reported. We have observed eighteen cases with primary tumor of the ureter at the Mayo Clinic and they are now being reviewed by Dr. Counseller and Dr. Cook, preparatory to reporting them. Of the eighteen cases, the preoperative diagnosis was made in only ten. In the last few years the accuracy of diagnosis has improved as the result of excretory urography. In two of our cases the patient was operated on for hydronephrosis and the tumor in the ureter was found subsequently. In another case the kidney was removed elsewhere for hydronephrosis. It is evident, therefore, that when pyelectasis is visualized in the excretory urogram, the site of ureteral obstruction should be determined and neoplasm excluded. Most of these tumors occurred among male patients. According to the degree of malignancy, seven tumors were graded 2, seven were graded 3, one was graded 1, and one was graded 4. An angiomatous tumor occluded the ureter in one case. Granuloma of the ureter may also occur and be large enough to simulate a neoplasm. Distinguishing primary tumors from secondary tumors of the ureter is an essential step in diagnosis. In two cases in which we made the diagnosis of tumor of the ureter, the lesion proved to be secondary to a primary papillary epithelioma of the renal pelvis, which we failed to find during the preliminary examination.

The prognosis in these cases has not been very good. Most of the eighteen patients were dead within three years after operation and several died in less than a year. It is possible that removal of the portion of the bladder surrounding the ureteral opening may give somewhat better results, but it is doubtful. That the condition is, fortunately, rare is shown by the fact that only eighteen instances were found at the Clinic in many thousand abdominal operations. Nevertheless, it does occur often enough so that one must be on the lookout for it.

Dr. W. H. Condit (Minneapolis): What did the patients die of?

Dr. Braasch: Early metastasis into the surrounding lymphatics.

Dr. Foley: On October 12, approximately three months after operation, a small mass of induration high up in the right side of the pelvis could be felt on vaginal and rectal palpation. Whether this represents induration of the repair process or persistence or recurrence of the ureteral neoplasm cannot be said at this time.

The meeting adjourned.

A. G. Schulze, M.D., *Secretary*

Meeting of December 14, 1938

The regular monthly meeting of the Minnesota Academy of Medicine was held at the Town and Country Club on Wednesday evening, December 14, 1938. Dinner was served at 7 o'clock and the meeting was called to order at 8:10 p. m. by the vice president, Dr. Carl B. Drake, in Dr. LaVake's absence. Forty-eight members were present.

Minutes of the November meeting were read and approved.

Upon ballot the following men were elected as candidates to active membership in the Academy:

Dr. John Lepak	Saint Paul
Dr. Kenneth Phelps	Minneapolis

This being the annual meeting, the following were elected as officers for the year 1939:

President	Dr. Carl B. Drake, Saint Paul
Vice President	Dr. James Johnson, Minneapolis
Secretary-Treasurer	Dr. A. G. Schulze (reëlected)

The scientific program followed.

FILTERABLE VIRUSES IN RELATION TO TUMORS AND MALIGNANT GROWTH

Robert G. Green, M.D.
University of Minnesota
Minneapolis

Abstract

The principal defining characters of the ultramicrobes are a submicroscopic size and obligate parasitic growth within living cells. Their nature may be reasonably explained if it is recognized that the degenerative processes apparent in visible parasites are operative also in the world of microscopic parasites.

Typical of retrograde changes under conditions of parasitism are the modifications observed in the tapeworm, which, adapted to a parasitic existence in the gastrointestinal tract of animals, has entirely lost a digestive system of its own. It has long been my concept that bacteria and other microbes, in adapting themselves to parasitic life within cells, lose many vital functions which are available to them in the surrounding protoplasm, thereby become correspondingly smaller, and degenerate into the submicroscopic parastitic particles that we call filterable viruses.

In their adaptations filterable viruses are similar to bacteria and protozoa. To perpetuate their kind, viruses, like other parasites, must order their parasitic existence so as to gain a host, reproduce, and escape to a new host. The passage of the yellow fever virus through the mosquito is almost a duplicate of the complex adaptation of the malarial protozoan. It is recognized that the present status of the malarial parasite has been reached through a long series of evolutionary adaptations. The same appears true in the case of the ultravirus of yellow fever. Throughout their adaptations, viruses exhibit general properties common to the visible bacteria and protozoa.

Viruses as a group show a great diversity, and range from particles of visible size, and obviously closely related to microbes, down through submicroscopic particles approximating the size of large organic molecules. From this viewpoint, the viruses seem to be an extension of parasitic forms into the submicroscopic world through a series of intermediate sizes. Viruses, from these general considerations, appear to be biological species which maintain themselves as do pathogenic bacteria or protozoa and are attached to these visible microbes by intermediate forms.

It is now becoming evident that many proliferative lesions and tumors in animals are caused by viruses. The development by viruses of an ability to cause the cells in which they live to divide and expand their world of growth must be regarded as an adaptation favorable to the existence of viruses. The development of properties for an intracellular existence must depend upon a high degree of conformity of the physiologic processes of the parasite to those of the host cell. This is shown generally by the marked chemical inactivity of all obligate pathogens as compared with saprophytic bacteria.

The conformity of the physiologic processes of the intracellular parasite to those of its host, as an adaptation for parasitic existence, would probably, to a marked degree, be one of similarity. In the tangled metabolic processes of virus and host protoplasm, a proliferative virus might well substitute for a similar aggregate in protoplasm of the host and become anchored as a part of the cell. While this concept is speculative, investigations in this field are yielding information that supports some such concept. Rous has shown that the virus of the rabbit papilloma, which is demonstrable in the benign growth, cannot be obtained from the cancerous proliferation which often develops therefrom. Transplants of the cancer, however, appear to immunize against the virus. Kidd has found that from the Brown-Pearce carcinoma of rabbits a foreign antigen can be extracted which will give immune reactions with the blood of a rabbit afflicted with the tumor. Evidence of this type is accumulating which points to an intimate association of viruses with certain malignant growths, and seems to indicate that in these cases the virus is in some manner fixed within the malignant cell. At the present time research on viruses and their relation to tumorous growths is very productive. A concept of virus-fixation as a cause of malignant growths offers a possibility that at least cancers of a certain type may

sometime be prevented by immunization against viruses which cause precancerous lesions.

Discussion

Dr. Moses Barron (Minneapolis): Dr. Green's paper covers a very fruitful field for investigation since the origin of cancer is still undetermined. Because of the many different theories, one has to be very careful in drawing too strict conclusions.

Some twenty-five years ago Dr. Ervin Smith published a great deal on the production of plant cancer. He produced experimental tumors on various plants like crown-gall by the injection of the bacillus tumefaciens. At that time he brought out the parasitic theory of cancer, that is, that cancer is caused through the stimulation of cells by filterable viruses or bacteria. The work presented here tonight by Dr. Green is interesting in that he shows that certain types of papillomatous tumors in rabbits may be produced from the injection of what he considers a filterable virus obtained from such tumors. One has to think of the possibility that these tumors are produced from a simple irritation of some chemical substance. It is well known that certain chemicals, like tar, etc., will produce cancer when applied to the skin of different animals. I understand Dr. Green to say that not all animals inoculated with the filtrate of these papillomatous tumors develop papillomas. I believe he said that perhaps only one in a thousand or one in many thousand animals will result in cancer; that is, even if the tumors are produced, only a very small percentage will go on to the malignant stage. In animal experiments the cancer, therefore, may be not the direct result from the virus, but rather indirectly the result from the cellular proliferation which was brought about by the virus. There is one question which always comes to my mind whenever virus is presented as causing cancer. Since cancer cells develop from normal cells through a gradual transition during cellular proliferation, are we going to assume that the normal proliferation in growth and healing is also caused by a certain virus? Personally, I am not yet convinced that viruses in themselves produce cancer. Dr. Green's presentation is intensely interesting, but we must be careful in drawing too broad conclusions from results thus far obtained.

Dr. F. R. Wright (Minneapolis): A year ago in Philadelphia a paper was read at a research meeting giving the idea that malignant growths were due to protein colloid poisoning; that these individuals lived on protein-colloid-containing foods and that it was the over-use of the protein foods which tended to produce the growths.

Dr. C. B. Wright (Minneapolis): I would like to ask Dr. Green what progress has been made in can-

AN EFFECTIVE TREATMENT FOR

TRICHOMONAS VAGINITIS

An effective treatment by Dry Powder Insufflation to be supplemented by a home treatment (Suppositories) to provide continuous action between office visits. Two insufflations, a week apart, with 12 suppositories satisfactorily clear up the large majority of cases.

SILVER PICRATE • Wyeth •

cer studies from the standpoint of Dr. Rowntree's work on wheat germ oil?

Dr. Arnold Schwyzer (Saint Paul): I wonder about an experiment made by Lanz, later Professor of Surgery in Amsterdam, Holland; whether it would come in this study. The infectious character of a growth like a wart was accepted a long time ago by many. Lanz rubbed a wart into the skin of the back of his hand in a manner to form the letter "W." After some time one could see warty ridges on his hand in the form of the letter "W."

Dr. Green (in closing): I did not intend to suggest that viruses are the cause of all proliferation. As parasites they take advantage of the proliferative property of cells and stimulate it for their own benefit. Certain insects are capable of stimulating proliferation of plant tissues to form a gall which serves as a favorable habitat for their offspring.

The request for further information about vitamin E and colloid malignancies I cannot satisfy, as I do not know how far this work has been extended since the reports mentioned.

The comments of Dr. Schwyzer regarding warts are very significant. Little work has been done in attempts to demonstrate that proliferative growths in human beings are due to viruses. It is recognized that a wart is one human proliferative lesion caused by a virus infection.

BOOK REVIEWS

Books listed here become the property of the Ramsey and Hennepin County Medical libraries when reviewed. Members, however, are urged to write reviews of any or every recent book which may be of interest to physicians.

YOU CAN SLEEP WELL. The A B C's of restful sleep for the average person. Edmund Jacobson. 269 pages Illus. Price $2.00. New York. Whittlesey House, 1938.

Confronted with the dilemma of sacrificing accuracy for palatability, the author has attempted in "You Can Sleep Well" to be all things to all men. One day while riding on a train, a phantom traveling salesman sold the author the idea of collaboration, which probably explains the hyperkinesis and hypertensiveness of the style of writing. In the first sixty pages, this traveling salesman is allowed to run rampant through doctors' offices and over golf fields seeking a cure for insomnia. He tries the gamut of "cures" from ovaltine to aspirin, but without success. Then in desperation, on the verge of a nervous breakdown, he tries the new method of "progressive relaxation," and finally gets his much needed sleep. If the lay reader has difficulty in finding the gold in this large, hard nugget, let him turn to pages 92, 103, 114, 121, 130 and read the instructions on how to relax carefully, and then if he still remains awake, turn to the last chapter on "How the body falls asleep."

The reviewer hopes that the second edition will be written in the simple clear style of his first book, "You Must Relax." Max Seham.

ESSENTIALS OF OBSTETRICAL AND GYNECOLOGICAL PATHOLOGY. Douglass and Faulkner, St. Louis: C. V. Mosby Co., 1938.

Douglass and Faulkner, in their book on gynecological pathology, have composed an easily read manual covering the fundamentals of the subject. The book should be of especial value to students and to those practitioners who desire a quick, fairly comprehensive review of a specialized field. The text is well illustrated.

* * *

EXPERIENCES IN THE MANAGEMENT OF FRACTURES AND DISLOCATIONS. Philip D. Wilson, M.D. 1036 pages. Illus. Price, $5.00. Philadelphia: Lippincott, 1938.

This book is, without doubt, one of the most important works dealing with the fracture problem which has been published in recent years. It is not a textbook but is a series of monographs setting forth the experiences of a number of experts in the care of fractures. Over four thousand fractures and dislocations occurring on the fracture service of the Massachusetts General Hospital between the years 1923 and 1930 were studied and the final results were evaluated. Every case in which the end-result has been determined is summarized and the history, examination, the original treatment and the final treatment are given. At the end of each section there are the conclusions which have been arrived at as the result of the study of the individual type of fracture. The mere fact that a group of men have been willing to set down the unprejudiced account of their experiences in the care of their fractures without any regard to good or bad results is enough to recommend this book as a valuable addition to any surgeon's library.

THE SIGNIFICANCE OF NORMAL BLOOD SUGAR IN THE TREATMENT OF DIABETES MELLITUS*

JOHN R. MEADE, M.D.

Clinical Assistant in Medicine
University of Minnesota Medical School
Saint Paul, Minnesota

THE common teaching in medical schools until recently has been that adequate treatment of diabetes mellitus has two objectives—to maintain the blood sugar within normal limits and to keep the urine sugar-free. The normal level of blood sugar has been stated to be from 90 to 140 mg. per 100 c.c. of blood. This estimation refers not only to glucose but also to the other reducing substances in the blood which are generally included in the blood sugar reading. During the past ten years there has arisen a controversy as to how significant it is in the treatment of diabetes mellitus to achieve a normal blood sugar level, and the literature contains many pertinent observations by men who have been interested in the subject.

When diabetes was first described and treatment by diet alone instituted, it was very difficult to keep the blood sugar within normal limits except by reducing the patient to a state of severe malnutrition which usually led to coma and death unless the diabetes was very mild. Since the advent of insulin and since protamine zinc insulin has been available, malnutrition has ceased to be a problem. In fact, we are able now to maintain the diabetic at his ideal weight, rather than below this point, by giving enough insulin to keep the urine sugar-free without causing hypoglycemia. Experience has shown that it is difficult, in some patients, to keep the blood sugar within normal limits without causing hypoglycemic reactions.

Sugar usually appears in the urine when the blood sugar reaches a level of 170 mg. per 100 c.c., and this reading is taken by most authors to be the upper limit of renal threshold for glucose. In the treatment of diabetes we all encounter patients who manifest no glycosuria but who consistently have a level of blood sugar as high as 350 mg. per 100 c.c. These people are usually past the fifth decade of life and seem to remain in good health as long as the urine is sugar-free. Various reasons are given for the development of hyperglycemia in some patients and not in others. Porter and Langley,[6] after doing glucose tolerance curves on fifty normal individuals ranging from thirty to eighty years in age, concluded that the curves must be interpreted with regard to the age of the patient as well as to the height of the curve, because their study showed that the older the patient, the higher the curve, and the greater lag that occurred before it returned to normal.

John[2] compared the fasting blood sugar and urea of a thousand patients without diabetes and found a slight but uniform rise of blood sugar with each succeeding decade. The retention of blood urea was higher in the later decades also, but the blood urea was much higher in some of the cases than in others of the same age. This suggests that a common underlying factor, such as renal insufficiency, did not govern both of these elements. Mosenthal[5] thinks that the reason for higher levels of blood sugar without glycosuria in diabetic patients of advanced age is due to the greater power of reabsorption of the kidney tubules of the glomerular filtrate rather than to the lowering of the excretory power of the kidneys.

---

*Read before the Ramsey County Medical Society, St. Paul, Minnesota, November 28, 1938.

Before the advent of insulin the average age at death of patients with diabetes was 44.8 years, whereas in the period since insulin has been available the average age at death has risen to 62.8 years. At the same time the incidence of arteriosclerosis in diabetes has risen, probably as a result of the fact that the patient with diabetes lives on into the age group in which we almost always find some degree of arteriosclerosis even in the non-diabetic person. It has been thought by many that hyperglycemia was directly responsible for arteriosclerosis in association with diabetes, but this opinion is not held by Joslin.[3] He feels that a high blood cholesterol has more to do with the production of arteriosclerosis than does hyperglycemia, and states in substantiation that children with a level of blood cholesterol higher than 300 mg. per 100 c.c., show evidences of arteriosclerosis and other disturbances of fat metabolism. It would seem then that hyperglycemia from the standpoint of production of arteriosclerosis is not as important nor as dangerous as has been described.

Soskings, Katy, Strouse, and Rubinfeld[7] have shown that in elderly individuals with diabetes and cardiovascular disease the symptoms of insulin hypoglycemia could be reproduced by lowering the carbohydrate fraction of the diet to a low level.

Infection, along with arteriosclerosis, is one of the major factors in the production of gangrene in diabetes, and it has long been thought by many that hyperglycemia makes the tissues more susceptible to bacterial invasion and growth. Handsman,[1] however, found that staphylococci did not grow any better in blood that contained as high as 1 per cent of dextrose than in normal blood, and furthermore that blood with a higher concentration of dextrose did not have a lower bactericidal power. These observations lead us to believe that a diabetic with hyperglycemia is not more prone to diabetic gangrene than is the diabetic who maintains a normal level of blood sugar.

According to Joslin,[4] our reasons for trying to establish a normal blood sugar without glycosuria in the diabetic are as follows: (1) Normal values are obviously the best. (2) Hyperglycemia is a stimulus to the secretion of insulin, and we do not want the impaired island tissue to be overworked. (3) Removal of glycosuria proves complete utilization of the carbohydrate fraction of the diet. (4) Hyperglycemia implies that the tissues also contain a higher percentage of sugar than normal, which supposedly leads to lack of tissue repair as well as lack of resistance to infection, and causes degenerative phenomena of the blood vessels and nerves. In regard to the last statement, however, Joslin does not find any difference in the speed of wound healing or increase in wound infection following operation in patients who have hyperglycemia without glycosuria. Joslin[4] says further: "We do not believe that a hyperglycemia up to 200 mg. per 100 c.c. of blood is particularly harmful to a diabetic provided that the urine is sugar-free, because this is proof that he is not eating his carbohydrates uselessly."

Wilder[9] states that he has seen two cases of peripheral neuritis develop in diabetics in whom the blood sugar levels had been lowered to normal or nearly normal values. The patients recovered when the insulin dosage was decreased and there was subsequent hyperglycemia but no glycosuria. Sunderman, Austin, and Williams[8] noted that some patients with diabetes had insulin shock reactions with blood sugar levels of 200 mg. per 100 c.c. of blood if the value for blood sugar fell from a higher level after the administration of insulin.

I have attempted to analyze the courses of fifty-four patients with diabetes, about 90 per cent of whom have been taking only one dose of protamine zinc insulin before breakfast and who have maintained a urine free from sugar (Table I). All of these patients are on a well-regulated diet, consisting of a basal number of calories plus various percentages, depending on the type of occupation of the patient. Of this group all the patients over thirty years of age have a hyperglycemia, which is correspondingly higher in the older patients. At various times when I have endeavored to reduce the hyperglycemia of these patients I have met with hypoglycemic reactions, together with most strenuous objections on the part of the patients. Subjectively they are irritable, and they neither feel as well nor do their daily work as well as when

TABLE I. AVERAGE FASTING BLOOD SUGAR READING IN FIFTY-FOUR WELL CONTROLLED DIABETIC PATIENTS

Age Groups	Number of Cases in Each Group	Average Blood Sugar in Mgs.	Clinical Arteriosclerosis	Slight to Moderate Gangrene
30-39	14	151	2	0
40-49	13	159	7	1
50-59	12	172	9	4
60-69	9	194	9	6
70-79	6	224	5	4

the hyperglycemia is present. These patients all have maintained their normal weight.

I think we all have seen older patients who have had anginal seizures when the blood sugar was reduced to normal although there were no other clinical signs of hypoglycemia.

We must insist, of course, that all diabetics, except those in the older age group with coronary disease, keep the urine sugar-free, because prolonged glycosuria, if it is at all marked, will end disastrously for the patient. Dehydration with consequent lowered resistance to infection, malnutrition, acidosis, coma and possibly death are what we may expect of prolonged glycosuria.

In conclusion, I wish to emphasize that a blood sugar within normal limits and a urine free from sugar are ideal conditions for the patient with diabetes only as long as he remains in a good state of nutrition and does not have hypoglycemic reactions. However, I think we should not strive to achieve a normal status in the glucose level of the blood in diabetes at the expense of the patient's feeling of well-being. Although much of the teaching regarding the treatment of diabetes mellitis has been to the contrary, men with large experience in this field have found that hyperglycemia without glycosuria is not harmful to patients with diabetes. My own experience substantiates this to the extent that I feel that hyperglycemia without glycosuria does not cause as much harm to the patient as has been thought in the past and that arteriosclerosis and gangrene, so dreaded in diabetes, are not due alone to hyperglycemia without glycosuria.

ACUTE SURGICAL CONDITIONS OF THE ABDOMEN*

J. M. HAYES, B.S., M.D., M.S., F.A.C.S.

Assistant Professor of Surgery, University of Minnesota
Minneapolis, Minnesota

NO branch of surgery yields greater mortality than acute surgical conditions of the abdomen. Preoperative diagnosis here is often most difficult and may be impossible. Good surgical judgment, perhaps, is the most important factor in reducing morbidity and mortality in these cases.

Acute surgical conditions of the abdomen have been confused with the following: lead-poisoning; gastric crisis of tabes; diabetic acidosis; diaphragmatic hernia; central pneumonia; and coronary and mesentery thrombosis.

It has been suggested that pain, nausea and vomiting with constipation continuously for more than six hours should lead one to seriously consider surgery.

---

*Read before the Northern Minnesota Medical Association, Crookston, Minnesota, August 29, 1938.

The presence of diarrhea may obscure or change the entire picture. An acute enteritis may and frequently does lead to a poorly advised laparotomy. Such an operation usually not only does not better the patient, but may change a rather mild condition into one which is very serious. On the other hand an acute enteritis should be followed closely lest the picture change later into an acute surgical condition.

A good history and physical examination with all applicable laboratory assistance may give us a clue to otherwise very indefinite conditions.

In no other condition is it more imperative to make the diagnosis early. Disastrous changes may take place rapidly and the safest time for operation may have slipped away if the diagnosis is not made early. Incorrect diagnosis and poor surgical judgment has led to many unnecessary laparotomies. This fact has done much to bring the profession into disrepute with the public.

Appendicitis is still the most frequent surgical condition in the abdomen. It constitutes about 50 per cent of all abdominal surgery. In spite of our recent improved aids in diagnosis and technic the mortality in appendicitis is on the increase.

The mortality from appendicitis in the United States in 1920 was 11,000.[1] In 1937 it was 20,000. Why there should be this increase in mortality we do not know. No doubt self medication is a large factor. Also failure of the patient to report to the physician at a time favorable for cure plays a large part in this increasing mortality. However, the profession must take at least some part of the blame for this almost tragic truth.

In some parts of the country an educational program is being put on to teach the public how they can aid in reducing this mortality. Perhaps this should be made national in scope.

In the typically severe, acute case of appendicitis there is usually general agreement among the physicians and surgeons that immediate operation is the treatment of choice. In the more indefinite case the patient may be slow to report and the physician may have difficulty making a diagnosis.

In general, pain, nausea and vomiting, right rectus rigidity, and a high leukocyte count in a patient who has been well up to a few hours previously should strongly suggest an acute surgical appendix.

With a retrocecal appendicitis the muscle rigidity may be almost absent. The pain, nausea and vomiting may be slight or almost absent, yet we may have a severe appendicitis. In this case if other conditions are quite well ruled out and the leukocyte count has risen rapidly over a short period of time, a surgical appendix must still be seriously considered. If the leukocyte count rises to twelve or fifteen thousand or above and other symptoms point to appendicitis one is usually safe in advising appendectomy.

When these patients come to us late and the possibility of a ruptured appendix is likely, there is considerable difference of opinion among the best surgeons as to how best to treat them.

If there is good evidence of localization and symptoms are subsiding one may be justified in waiting for the inflammatory process to cool down before opening the abdomen. This, though, is hard to determine definitely. We cannot always be sure whether the appendix is ruptured or not. So often the process continues with no let-up and slight localization that the treatment of these cases is still in dispute.

The surgeon who has seen a number of these patients go on without localization or any let-up in symptoms to a fatal end usually advises operation as soon as the diagnosis is made. Personally, I favor the latter course. Unless there is a well walled off abscess and the appendix is plainly part of that wall, I remove the appendix even in the face of perforation. Good drainage is instituted and I believe much can be done to promote drainage and lessen the virulence of the infection by the application of a large, wet, antiseptic pack.

Acute cholecystitis is the most frequent upper abdominal surgical condition. In acute cholecystitis we do not include the acute gallstone colic in which a hypodermic of morphine relieves the pain and the patient goes on to an uneventful recovery. Nor do we necessarily include the patient who shows improvement in the course of one or two days.

We refer here only to the patient who goes on to progressively increasing acute inflammatory symptoms, as evidenced by increasing temperature, leukocyte count, and general toxicity. In the treatment of these cases there is much difference of opinion among the leading surgeons of the world.

It is my belief that patients most seriously ill with acute cholecystitis do not commonly reach the great surgical centers. They are often too sick for distant transportation. I believe the reason for such great divergence of opinion among surgeons in the treatment of these cases is that they are not talking about the same type of cases.

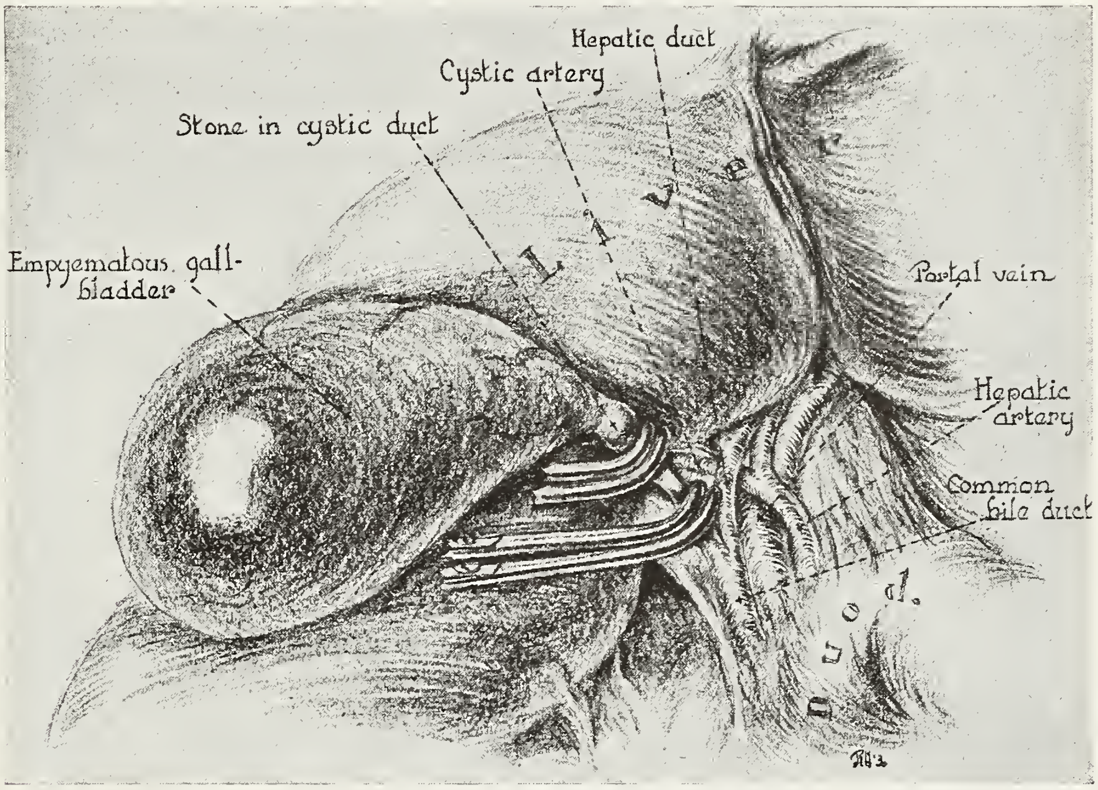

Fig. 1. Drawing of acute empyema of the gallbladder. This shows the stone in the distal cystic duct pressing on the cystic artery. The portion of the cystic duct between the clamps appears about normal. The inflammatory process here is confined almost entirely to the gallbladder. It has not yet become adherent to adjacent organs.

Such men as Everts Graham advise conservative treatment, waiting to operate until the acute process cools down. He states that he has had a very small mortality in those treated conservatively. On the other hand Lahey says, "The more experience I have with acute cholecystitis the more I lean toward immediate operation, and total removal of the gallbladder when it can be done."

Sir James Walton of London gives a summary of this condition which my experience leads me to regard most favorably. He concludes with the statement that this operation is one of difficulty and associated with much risk. I therefore unhesitatingly advise that the onset of acute cholecystitis should be regarded as a grave emergency and that immediate operation should usually be advised.

Payne of Virginia found twenty-nine gangrenous gallbladders in sixty-five cases of acute cholecystitis.

Saunders of Tennessee reports forty-five perforations with 17.4 per cent mortality.

Huer of Yale in a series of acute cases reports 20 per cent perforations and gangrenous gallbladders.

Some surgeons have been fortunate in having most acute cases localize and subside; others have had just the opposite experience with cases that originally appeared about the same. Some years ago the late Dr. Dennis of St. Paul called attention to the fact that a stone in the distal end of the cystic duct usually produces pressure on the cystic artery and is likely to result in gangrene or empyema of the gallbladder. Close to the common duct the cystic artery and duct are far apart, but as they approach the gallbladder they approach each other. A stone at this latter point is more likely to interfere with the circulation of the gallbladder. No one can be sure before exploring where the obstruction of the cystic duct may be.

Personally I have had thirty cases with obstruction in the distal end of the cystic duct or pelvis of the gallbladder. All of these patients showed evidence of gangrene or empyema of the gallbladder. Nineteen were operated within seventy-two hours with no mortality and very little greater morbidity than in the ordinary chronic gallbladder. The twentieth patient, operated upon after two weeks, died. Of the remaining ten cases the gallbladder ruptured into the peritoneal cavity in three, one of the three dying before we could open the abdomen. The other two recovered after a very stormy convalescence. Of the remaining seven, perforation occurred posteriorly and pus burrowed upward posteriorly behind the liver, through the diaphragm and into the pleural cavity. Pus and bile were aspirated from the pleural cavity. Later the gallbladder was removed with much difficulty. Of the remaining six, three were drained, and the gallbladders had to be removed later. The remaining four drained for periods of from two to six months. Two closed after drainage but had to be reopened two or three times before final closure. All of these patients were very sick, with gradually increasing symptoms. The leukocyte count in all these cases ranged from 15,000 to 27,000.

This experience has led me to favor the advice of Lahey and Sir James Walton, that these gallbladders should be removed as soon as the diagnosis is made, or at most during the first twenty-four to forty-eight hours.

Intestinal obstruction is a frequent abdominal surgical condition. It carries a high rate of mortality. Recent advances in our knowledge of this condition are of great assistance. The knowledge that an alkalosis develops rather than an acidosis indicates what fluids should be administered. Nasal suction is a great help but may be used to disadvantage and unavoidable surgery may be delayed. Nasal suction may relieve the patient and fecal material may be obtained with enemata, still there may be a closed loop bound down firmly by adhesions that can be relieved in no way except surgically. In these cases every hour of delay increases the risk. Early surgery, relieving the obstructing bands or ileostomy, should give good results.

In children intussusception is quite often the cause of obstruction. They may be relieved by traction or non-operative procedure but operation should not be long delayed, if relief is not otherwise readily obtained. In all cases of obstruction the x-ray is invaluable in determining the presence and location of the obstruction.

Perforating ulcers of the gastro-intestinal tract are surgical and exploration should be made at the earliest possible moment. During the war general orders were given to refrain from operation in cases of perforation when it could not be undertaken within the first twenty hours.

Nature frequently does a good job of sealing over the perforation. After twenty hours we frequently tear loose this sealing process and spread the infection. Abel has said of the perforating peptic ulcers that he has lost none operated upon during the first six hours after perforation and has had only one live after twenty-four hours. If done early, drainage of the wound is usually not necessary; if late it is advisable to drain through a low stab wound. Severe pain, board-like rigidity of the abdomen, shock, and collapse are usually present. Closing the perforation and covering it with a tab of fat is usually sufficient in emergency cases.

Ruptured ectopic pregnancy is fairly common. A history of pregnancy, if obtainable, is valuable. Frequently this cannot be obtained. Bleeding from the vagina is next most important, but may not be present. There is usually sudden, severe pain with distention. Muscle rigidity is not usually so marked as in appendicitis. The pulse is frequently rapid and thready. The temperature may be subnormal, and symptoms of collapse may be present. If on the right side it may be impossible to differentiate from an acute appendicitis. In appendicitis the leukocyte count is usually higher in relation to other symptoms. Surgery is indicated as soon as the diagnosis can be made.

Acute pancreatitis is somewhat rare. The diagnosis is usually difficult. It is usually thought to be secondary to cholecystic disease. If the diagnosis can be definitely made, the patient may do well under conservative treatment. Cholecystotomy and cholecystectomy are frequently done in these cases, sometimes because gallbladder disease cannot be ruled out, and again because the surgeon considers this the best means of curing the condition.

In the acute hemorrhagic type, no treatment yet attempted has been very effective. Here again the gallbladder is frequently drained with the hope of possible relief.

Twisted ovarian pedicle is quite rare, yet frequent enough to give us some worry. On the right side it is frequently confused with appendicitis. The pain here is usually more continuous but the muscle rigidity is not so marked as in appendicitis. The abdomen is more distended. The leukocyte count is not so high in proportion to other symptoms. The pain usually continues until relieved by operation.

Jaundice may exist with or without pain. Intermittent jaundice without pain, with a history of chills and fever, general malaise, bile in the urine and clay colored stools, usually means the catarrhal type. However, a large stone in the gallbladder with secondary inflammatory process may produce enough pressure on the common duct to give this same picture. The cause of a continuous jaundice for more than two weeks must be definitely determined if operation is contemplated.

Gradually increasing jaundice for over six weeks, continuously, should suggest carcinoma of the head of the pancreas. Stone in the common duct may give much the same picture, but usually the jaundice is somewhat intermittent and pain is more likely to be present. In any event if operation is to be attempted one should not wait more than two weeks from the time of onset of the jaundice.

In all acute progressive conditions of the abdomen the resistance of the patient rapidly lessens. No other type of surgery requires more careful preparation of the patient, choice of anesthetic, or handling of the viscera once the abdomen is opened.

TORSION OF THE OMENTUM AND APPENDICES EPIPLOICAE*

Report of Two Cases

BENJAMIN F. DAVIS, Ph.D., M.D.
Duluth, Minnesota

THE first case is one of torsion and beginning gangrene of the omentum.

The patient was a white woman, forty-five years of age. She entered the hospital on the afternoon of June 26, 1930. On the preceding night, she had been awakened by a sudden severe pain in the right side of the abdomen, radiating to the right side and back, with vomiting. This was very soon followed by the development of extreme tenderness and moderate distension.

General examination was negative. There was extreme tenderness, with muscle spasm and rigidity, in the right upper quadrant of the abdomen. The temperature was 99.6°, pulse 120. The urine was normal.

The diagnosis of an acute abdominal condition, requiring immediate exploration, was made, with a high-lying appendix the probable condition.

The abdomen was opened under spinal anesthesia. There was exposed immediately a mass of omentum, about 15 cms. long, 8 cms. wide and 3 cms. thick, arising by a pedicle from the omentum of the transverse colon, near the hepatic flexure; the pedicle was twisted rather tightly several times on itself. The strangulated mass of omentum was mottled, dark purplish-red in its upper portion and almost black distally. It was quite hard and friable. The pedicle was clamped, cut and tied with catgut. The appendix lay to the immediate right of the cecum and was adherent to the cecum and mesocecum. It was quite hyperemic and was, therefore, removed. The abdomen was closed in layers, without drainage. The patient made an uneventful recovery.

The outstanding features of this case were the sudden onset, with vomiting, the fairly constant, severe pain, radiating to the back, and the extreme local tenderness.

No preoperative blood study was made.

Compared with other acute surgical lesions of the abdomen, torsion of the omentum is relatively rare. Jeffries[4] in 1931 collected 169 cases from the literature and reported four new cases. I have found approximately twenty additional cases published since 1931, which would make a total of about 193 cases.

The cause of torsion of the omentum is somewhat speculative; however, there are certain fairly constant factors which seem to be present in most of the cases. In Jeffries' series of 169 cases, 147 were associated with right inguinal hernia. Niemeier,[6] writing in 1935, distinguished two types of the disease: (1) primary or idiopathic torsion, comprising about 13 per cent of the cases and distinguished by the absence of adhesions about the omentum, and (2) so-called secondary torsion, comprising about 87 per cent of the cases. In the majority of this 87 per cent, the distal end of the omentum was adherent in a hernial sac, while in a small minority the adhesion was to some other point in the abdomen.

---

*Read before The Duluth Surgical Society, February 24, 1938.

Other factors involved in the production of this condition are: (1) an exceptionally large omentum; (2) a long pedicle; (3) a narrow attachment of the pedicle; (4) a relative increase in the bulk of the distal portion of the omentum, as by a deposit of fat, cyst formation or edema; and (5), as stated above, a point of distal fixation. It is evident that the importance of these various factors varies in different cases. Each may be the predominating cause at times, although, doubtless, the torsion is produced usually by a combination of causes. Farr and Bachmann[2] believe that the first 90° of torsion is produced by peristaltic action and then, since the veins are longer than the arteries, and more easily compressed, as venous congestion develops, the torsion tends to increase correspondingly. This idea is speculative, unsupported by experimental evidence, but should be considered in conjunction with the factors commonly found in association with the disease.

The involved portion of the omentum undergoes changes relative to the degree of torsion and the duration of the disease. There may be simply marked passive congestion or, at the other extreme, complete necrosis. At the meeting of the Western Surgical Association in Madison, Wisconsin, about five years ago, Dr. David Straus of Chicago reported a patient on whom he had operated a considerable period after the onset of symptoms. He had pulled out practically the entire omentum, black and necrotic, through a small abdominal incision.

The signs and symptoms do not permit of an accurate preoperative diagnosis and the correct diagnosis is practically never made before operation. In a series of seven cases reported by Farr and Bachmann,[2] the preoperative diagnoses were as follows: (1) acute cholecystitis; (2) subacute cholecystitis or perforating gastric ulcer; (3) acute appendicitis; (4) acute appendicitis; (5) acute cholecystitis; (6) undetermined; (7) chronic appendicitis (acute exacerbation). The signs and symptoms are those of an acute abdominal emergency. Treatment is surgical and the prognosis following treatment is good.

The second case is one of torsion of an appendix epiploica.

The patient was a man, thirty years of age. He stated that, at about noon of the day of examination, he had been seized with a sudden severe pain in the left lower quadrant of the abdomen which had persisted. On examination, there was found a localized area of acute tenderness, with muscle spasm, in the left lower quadrant of the abdomen. The W.B.C. was 18,700, pulse rate 96, temperature 98.6°; there was no nausea or vomiting. The patient's gallbladder and appendix had been removed some years previously.

A probable diagnosis of acute diverticulitis was made and the patient sent to the hospital.

He was operated on about 5:15 P. M. of the same day, under ethylene anesthesia. The abdomen was opened by a muscle-splitting incision in the left lower quadrant. Lying in close contact with the parietal peritoneum, at a point directly under the area of tenderness located clinically, was an appendix epiploica, which was a deep purple in color and apparently the seat of intense passive congestion. No definite sac connecting it with the lumen of the bowel was found although it was connected to the bowel by a narrow isthmus which was tightly twisted on itself by several turns. This was clamped, cut and the stump was buried with a Lembert suture. No other abnormality was found. The abdomen was closed in layers without drainage. The patient made an uneventful recovery.

The pathologic diagnosis by Dr. A. H. Wells was as follows:

Gross.—Specimen consists of an appendix epiploica measuring 2.3 x 1.3 x .5 cms. This shows a diffuse reddish discoloration and is unusually firm. However, the cut surface is unusually friable. It has a delicate pedicle measuring about 2 mm. in diameter which at this time is twisted through several complete turns.

Microscopic.—Sections show fatty tissue with severely congested vessels and areas of moderate neutrophilic infiltration and petechial hemorrhages.

Diagnosis.—Torsion of appendix epiploica with strangulation.

The first reported case of this condition was made by Littre[7] in 1703, who found a small white stone, the size of a pea, in the free abdominal cavity of a cadaver he was dissecting. No evidence was produced to show that this was an appendix epiploica but it appears to be accepted as the first case reported.

In 1924, Klingenstein[5] reviewed the history of the diseases of the appendices epiploicæ and reported four cases from the Mt. Sinai Hospital, New York. In two cases, the appendix epiploica was incarcerated in a hernial sac; in one, a twisted appendix was found adherent to an appendix vermiformis; in the fourth case, a twisted and acutely inflamed appendix epiploica was discovered at autopsy in a case of acute hemorrhagic pancreatitis. He found recorded at that time twelve cases of foreign bodies in the peritoneal cavity, presumably representing appendices epiploicæ; seventeen cases of intra-abdominal torsion; ten cases of intra-hernial torsion; thirteen cases of intra-hernial incarceration and three cases of intestinal obstruction due to adherent appendices epiploicæ.

In 1933, Patterson[7] again reviewed the literature and found fifteen additional cases of torsion of the appendices epiploicæ, four cases of intra-hernial strangulation and two cases of intestinal obstruction.

Fiske,[3] in 1936, again reviewed the literature, finding forty-two cases and adding two more. He omitted from his review all cases reported as torsion within a hernial sac and as loose foreign bodies within the peritoneal cavity.

The appendices epiploicæ are small pouches of peritoneum, filled with fat. Bland Sutton[7] described them as "localized pedunculated overgrowths of subserous fat directly continuous with the fat in the mesentery." They are found along the mesentery of the appendix and on the large intestine as far as the rectum. As a rule, they are arranged in two rows along the anterior and posterior longitudinal bands, and are more numerous and larger on the sigmoid than elsewhere. They vary in size and shape. Some have been reported 15 cms. in length, but the average is 3 or 4 cms. They may be cylindrical, flattened or lobulated. According to Robinson[7] they are present at birth. They have been credited by some writers with a protective function similar to the omentum. This conclusion was drawn because they have been found adherent to inflamed organs, but such relationship is a natural consequence of infection. Robinson pointed out that their structure is so unlike the omentum that it is improbable that they have the same function. Basing his idea on certain experimental studies, he suggested that they might have some function in relation to the movement and absorption of fluid from the large intestine. Patterson[5] has suggested that they might act simply as bumpers for the large intestine, fending this organ from the parietes and the other viscera, thus facilitating peristalsis. Their location and simple structure would support such a view. Cheever[7] bluntly states that the appendices epiploicæ are useless.

Appendices epiploicæ may be involved: (1) secondary to disease in adjacent or contiguous tissues; (2) by primary inflammation; (3) by torsion of the pedicle; (4) by incarceration in a hernial sac, with or without torsion; and (5) by undergoing calcification and appearing as loose bodies intraperitoneally, probably as a result of one or more of the above affections. No malignant changes have been reported in them. It has been suggested that some cases of apparent strangulation may be due to primary thrombosis of the vessels in the appendix.

From the clinical side, intra-abdominal torsion and hemorrhagic infarction of the appendices epiploicæ is a definite entity. The most characteristic symptom is abdominal pain over the site of the lesion, in many instances associated with localized tenderness. Nausea and vomiting are uncommon, as is also a palpable tumor, which has been described in only seven cases. Changes in the blood count have not been reported in most instances but there was definite leukocytosis in our case. The disease has resulted in complications causing death in three cases. It is readily relieved by surgical operation. The pre-operative diagnosis is difficult. In the presence of any obscure pain which is not explained by operative findings, explore the appendices epiploicæ. It may be that some of the cases of abdominal pain of unexplained origin, which subside spontaneously, may be due to strangulation of the appendices epiploicæ.

RATING OF DISABILITIES*

MYRON O. HENRY, M.D.
Minneapolis, Minnesota

THE principles of permanent partial disability estimation are well explained in McBride's textbook, entitled "Disability Evaluation," and the author, with his colleague, Dr. E. T. Evans, furnished the Minnesota-Dakota Orthopedic Society with a rating schedule for permanent disabilities of the extremities some years ago. More recently, Dr. George Dunn and others have published helpful papers on estimation of disabilities of the extremities. Loss of motion, muscular atrophy, loss of stability, shortening, and loss of sensation are generally considered in evaluating a disability, and the estimation of pain is really the only variable in rating disabilities of the extremities. While there are no fixed rules, conscientious surgeons, who are familiar with the law and with accepted methods of estimating disability, usually arrive at fairly uniform results in rating disabilities of the extremities.

Many other factors, which Stern has aptly called "variables," often enter into estimates of disabilities, and these variables, particularly, give rise to misunderstanding, uncertainty, and dispute. All of the surgeon's knowledge, experience, and sagacity may be required to evaluate such variable factors fairly and impartially.

Variable Factors

1. *Accident.*—Under the Minnesota Law the employee must be "injured by accident arising out of the course of his employment," separate statutory provision being made for occupational disease. Kessler defines accident, from the medical standpoint, as "an unexpected event, happening suddenly, producing a quick result, and coming from without." The disability need not be sudden, but may follow a trivial accident insidiously (as in osteomyelitis of the radius following a sliver in a finger).

The surgeon frequently must determine whether or not the present disability would inevitably result from the accident described. He must have due regard for the claimant's statements in order to be fair, yet he must "be alert to detect fraud, exaggeration, or malingering lest it be a reflection on his probity" (McBride). Disability produced by accidental means usually has some objective sign of external violence; it is usually produced immediately by the accident and should be continuous since the accident. Often the examiner must decide whether the particular accident described actually did produce the disability in question, or whether it probably or possibly did produce, or even could have produced, the disability.

2. *Congenital Abnormality.*—Sometimes anatomic variations and congenital malformations confound the evaluation of disability. Accessory bones in the foot are often mistaken for fractures, especially the accessory scaphoid (os tibiale externum), the accessory astragalus (os trigonum), and the bipartite sesamoids of the great toe. Open epiphyses may be mistaken for traumatic injuries—for example, the epiphysis of the iliac crest, the tip of the acromion process, and the separate tibial tubercle. Cervical rib and the scalene syndrome may produce disability similar to that of trauma. Malformations of the fifth lumbar vertebra, especially such as unilateral sacralization, non-fusion of laminæ, spina bifida occulta, and malposition of the postero-lateral articulations, cause much confusion when injuries are superimposed upon them. Some orthopedic surgeons believe that such malformations predispose to injury, or are more susceptible to injury, and that they recover more slowly from injury; others hold that they are merely incidental findings. Spondylolisthesis is particularly perplexing, and calls for thorough investigation before offering an opinion as to its traumatic origin. The majority of these cases are congenital with malformed zygapophyses, and forward dislocation obtains insidiously. Traumatic dislocation does obtain rarely, as in falls from a height when landing occurs in the sitting posture astride an object, but such cases may be expected to show later reactionary changes on the x-ray.

3. *Pre-existing Diseases.*—A number of comparatively rare bone diseases are conceded to be traumatic in origin, but, because they require

---

*Read before the annual meeting of the Minnesota State Medical Association, Duluth, Minnesota, June 30, 1938.

some time after injury in order to develop sufficiently for diagnosis, their origin may antedate the accident in question. Such are, Kienbock's disease, which is now generally admitted to be a traumatic malacia of the carpal semilunar; osteochondritis dissecans of the knee which develops a loose body; and Pelligrini-Stieda's disease, which is characterized by a semilunar bony formation over the internal condyle of the femur and results from trauma. Careful investigation is necessary to determine whether the trauma is old or recent in cases of snapping jaw, snapping hip, and even in snapping thumb which is due to the stenosing tenosynovitis of de Quervain. Similarly, bursitis, whether subacromial, olecranon, prepatellar or radio-humeral, is attributable to trauma which may be recent or remote. Cystic menisci, discoid cartilages, ganglions, and Baker's cysts are probably not due to any single trauma or accident.

Certain unrecognized diseases may produce injuries which the claimant honestly considers due to an accident. Osteoporosis of bone, especially of the spine, allows fracture from trivial causes; Charcot joints may give way unexpectedly, producing fractures; cerebral hemorrhage or epilepsy may cause a fall; the tabetic may fall while at work; and many bone tumors are found only after pathological fracture.

4. *Aggravation of Pre-existing Disease.*—This is the much abused *bête noir* of disability rating and is especially difficult to evaluate in many cases.

(a) *Arthritis.*—Aggravation of pre-existing dormant arthritis assumes external violence of sufficient intensity to produce changes, and the violence must have been applied directly to the area in question, with the symptoms of aggravation appearing within ten days of the accident. In the presence of pre-existing chronic focal infection (with advanced hypertrophic changes demonstrable by x-ray), it is exceedingly difficult to estimate the exact amount of aggravation caused by trauma, separate from the progress of the disease. Isolated joints, with arthritis excited or aggravated by trauma, present a problem which is simple compared to that of the spine. Here the function prior to injury is hard to establish even though hypertrophic spurs indicate disease which has been present for years. Unfortunately, there is still some honest difference of opinion regarding aggravation of pre-existing spondylitis. McBride is of the opinion that "hypertrophic changes are not traumatic, nor can they be aggravated except by actual fracture," while others hold that injury can, and often does, aggravate such pre-existing spondylitis to a disabling degree. It must be admitted by all, however, that aggravation, if it does obtain, is only temporary, and that such temporary aggravation must eventually cease, allowing the disease to continue its normal course. In the author's experience, such aggravation cannot reasonably be presumed to be disabling beyond three months without demonstrable fracture.

(b) *Gout.*—Arthritis urica, of course, is not caused by trauma, but a definite external injury to the affected part may excite an attack in the individual having the gouty diathesis. The attack must follow the trauma immediately, and is only temporary, seldom leaving permanent disability through aggravation *per se.*

(c) *Infection.*—One of the most difficult conditions to arbitrate is infection aggravated by injury. This is because the infecting injury is often trivial or overlooked, or because the injury superimposed upon pre-existing infection (or both) seemed of no importance at the time. The incubation period of bacteria becomes important in such cases, and this is reasonably four days for direct infections and three weeks for exacerbation of antecedent infection.

(d) *Osteomyelitis.*—Aggravation of pre-existing chronic, or healed, osteomyelitis by trauma is generally accepted. The established trauma, however, must be moderately severe and certainly should leave objective signs of external injury. The signs of renewed inflammatory activity should follow immediately, certainly within three weeks of the injury, and probably within three or four days.

(e) *Tuberculosis.*—Healed, or quiescent tuberculous joints, may be aggravated by trauma, and the same postulates obtain, namely, a proved accident with immediate and continuous disability, with renewed and continuous activity of the disease appearing within a few weeks.

(f) *Malignancy.*—Trauma may call attention to pre-existing tumors and, if sufficiently severe to cause hemorrhage or to actually injure the substance of the growth, may accelerate its progress. Presumably injury may precipitate metastases and thereby hasten the progress of the disease.

The foregoing are some of the factual variables presenting in cases to perplex the surgeon; there are also other less tangible variables which may operate to influence his judgment. Disfigurement, age, occupation, personal acquaintance, and various other psychic factors may prejudice the surgeon, unconsciously. The demeanor or attitude of the patient himself, the fee involved, or the prospect of advantageous business connections may sway his judgment, even though subconsciously.

The estimation of permanent impairment is not simple, and even with the aid of precise instruments of mensuration, it often cannot be reduced to mathematical exactness. A fair rating depends, first of all, on a careful history, thorough examination, reliable records, and a well-grounded knowledge of the subject; it also depends upon an unbiased and impartial attitude on the part of the surgeon. Experience reveals that many cases have improved with the return to activity that follows settlement of claims, reminding us that conclusions as to permanent disability should not be hastily drawn.

Furthermore, we should remember that the work of disability rating is perhaps seen, reviewed, and criticized more frequently by others than any other part of the surgeon's work. Considerable responsibility is thus thrust upon the surgeon rating disability; he must be fair to both sides and, at the same time, uphold his own integrity and the honor of his respected profession.

Discussion

Dr. R. M. Burns, St. Paul: Dr. Henry has presented a very instructive discussion on some of the unusual problems involved in rating industrial disabilities. His statement that "The conscientious surgeon usually arrives at a fairly uniform result in rating disabilities" is true and encouraging.

It is well when rating disabilities for one to keep in mind the purpose of the law. A New York Court Dispatch states concisely the purpose:

"The plain purpose of the Compensation Law is to make the risk of the accident one of the industry itself, to follow from the fact of the injury, and hence that compensation on account thereof should be treated as an element in the cost of production added to the cost of the article and *borne by the community in general.*"

The phrase "borne by the community in general' is of prime importance and should be carefully considered. Frequently, doctors, lawyers and others lose sight of this fact and imagine that they bear the burden of the law. In the end, the public pays.

Referees and commissioners want estimates of the loss of function expressed in concrete terms. They want the relationship between the injured part and the normal part expressed in terms of percentage. They do not want the estimate to be a guess and after all there is no reason why it should be a guess.

There are a number of good articles on the subject of rating and there are textbooks which are of assistance but we should not pay too much attention to schedules or textbooks. These are to be used as guides and not dictators in rating disability. The law does not demand that the rating be done according to any particular system or to the teaching of any particular authority.

I am sure that Dr. Henry hit the nail on the head when he said, "A fair rating depends first of all upon a careful history, thorough examinations, reliable records, and a well-grounded knowledge of the subject," to which I add, competent consultation.

The rating of industrial disabilities, particularly in the variable and difficult cases is no *one-man's* jom. The aggravation of existing diseases may easily involve every phase of medicine. Such conditions as Kienboeck's disease, arthritis, and malignancy immediately call for consultations from the roentgenologist and the pathologist.

An accurate diagnosis of the present injury and of the concurrent pathology are indispensable. A false conception of the patient's physical condition at the start will give trouble all through the case.

I wish to re-state Dr. Henry's closing remark: "Considerable responsibility is thus thrust upon the surgeon rating disability; he must be fair to both sides, and at the same time uphold his own integrity and the honor of his respected profession."

Every doctor should feel happy when his estimates have been declared satisfactory. He should also feel chagrined when he finds his estimates have been declared to be at variance with ordinary common sense. He must always bear in mind the interests of the employee, the employer and "the community in general."

SURGICAL CLINICS OF EUROPE

Some Personal Observations Made in 1937, 1938

LOUIS SPERLING, M.D.*

Minneapolis, Minnesota

WHILE making a tour of the clinics of western Europe, I was impressed by the friendly reception accorded American visitors, especially by those men who had visited in the United States. I was also impressed by the progress being made in the modernization of hospitals and by the attempts to carry out research in spite of obvious financial difficulties, and, in some places, in the face of political interference. There is a distinct effort being made throughout Europe to do good research. This is particularly true in the British Isles. I liked especially the clinics of England, Scotland and particularly those of the Scandinavian countries. The Scandinavian clinics now occupy the high position formerly held by the German and Austrian universities.

The British Isles

In London, I was fortunate in meeting Professor George Grey-Turner, chief of surgery at the British Post Graduate Hospital. The British Post Graduate Hospital is the newest and best equipped hospital in London. Here, graduate education in surgery is carried out in much the same manner as it is in our own centers for postgraduate study. In spite of being at the retirement age, Professor Grey-Turner came from Newcastle to assume the responsibilities of teaching in the surgical service at this hospital.

The ward rounds were most interesting and instructive. There were several cases of carcinoma of the esophagus in which radical resection by stages was being demonstrated. Such a case, operated on by Professor Grey-Turner in 1932, survived for nineteen months, succumbing subsequently to intercurrent nephritis. Carcinomas of the tongue are treated by teleradiation, followed in eight weeks by radical surgery if there is no marked decrease in the size of the lesion. The incision is made across the cheek, splitting the mandible if necessary. A Crile neck dissection is done if the nodes are involved. The Newcastle incision for acute appendicitis, popularized by Professor Grey-Turner, is the same as the McBurney incision except that the internal oblique muscle is cut, giving better exposure. In contrast to the policy at the University of Minnesota hospitals, every case of acute appendicitis is operated upon regardless of the stage of the disease.

The treatment of perforated ulcer was discussed at a meeting of the Royal College. The opinion, at this session, was that a conservative measure, *i.e.,* simple closure, was the treatment of choice. Professor Grey-Turner reported 365 cases of perforated peptic ulcer. In this series, the total mortality was 15 per cent; 267 cases of twelve-hour history had a mortality of 8.6 per cent; 119 cases, with only a six-hour history, carried a 3.6 per cent mortality. Professor Grey-Turner questioned the permanency of the results of splanchnic resection for hypertension. Mr. A. J. Watson, in charge of the department of orthopedics, is an ardent exponent of manipulative surgery. His attitude is typical of a large number of British orthopedists. He demonstrated the Hey-Groves apparatus for pegging fractures of the neck of the femur. By its use, only a small incision is necessary and good reduction is obtained. The only objection is that the procedure requires the insertion of a sharp nail dangerously close to the femoral artery. Mr. Watson-Jones of Liverpool later told the writer of a case in which he had punctured the femoral artery with this instrument.

Sir James Walton, at the London Hospital, is one of the few English surgeons who prefers the conservative operation of gastro-enterostomy for peptic ulcer, reserving gastric resection for the few cases in which complications follow the first operation.

Guy's Hospital, like all large London hospitals, has its own medical school. The students have two years preliminary training in the basic sciences, then go directly into a three-year clinical period. There is nothing corresponding to our internship. Practice is allowed after completion of the hospital work, but there is the opportunity to become a resident in the hospital in surgery, medicine or the specialties for a period of six months to a year. Mr. Ogilvie of Guy's Hospital, like the vast majority of continental surgeons, is an advocate of subtotal gastric resection for peptic ulcer.

---

*From the Department of Surgery, University of Minnesota. Minneapolis, Minnesota.

At St. Bartholomew's Hospital, Professor J. Patterson-Ross did an orchiopexy, anchoring the testicle in the scrotum on the opposite side of the septum. He stated that he had previously done a Keetly-Torek type of operation but had abandoned it in favor of this procedure. He is still doing total thyroidectomy on patients with angina pectoris. He also illustrated the conservative treatment of carcinoma of the breast with radium needles alone, recently described by Keynes, who claims 30 per cent cures over a five-year period; this percentage is the same as it was in previous years when radical surgical procedures were employed. There is considerable interest in peripheral vascular diseases at St. Bartholomew's. Conservatism is the rule in the surgical treatment of diabetic gangrene. Arteriograms, showing two types of Buerger's disease, were demonstrated: one with major occlusion of the popliteal artery or its branches, the other with peripheral arteritis. Most of the cases of Buerger's disease are being subjected to lumbar sympathectomy. A new unit for x-ray therapy at this hospital overshadows even our supervoltage machines. It has a maximum capacity of 1,600,000 volts.

In Liverpool, I visited with Mr. Watson-Jones, one of the younger English orthopedists, who has taken over much of Sir Robert Jones' work. He, like Professor Archibald Young, is opposed to skeletal traction, especially through the condyles of the femur or through the olecranon because of the commonly attendant complications in the knee and elbow joints. He insists that the whole of the semilunar cartilage should be excised and prefers to make a small posterior incision if necessary. Visco paste dressings (Unna's paste) are applied after the removal of plaster casts. Instead of an iron walking caliper, a rubber sponge is incorporated in the walking cast. Arthrodesis of the hip joint with a nail is advised for severe osteo-arthritis. There is, subsequently, surprisingly little disability in spite of the stiff hip.

In Edinburgh, Sir John Fraser and the late Sir David Wilkie were in charge of surgical services at the Royal Infirmary. They were using a combined streptococcus and gas bacillus serum in appendiceal peritonitis. For burns, both Fraser and Wilkie used 1 per cent rosanilin dye followed by 10 per cent silver nitrate. In his new experimental laboratory, Sir David Wilkie demonstrated his method of making massive block sections of whole organs. By this method, in a large series of cases, he was able to demonstrate areas of tuberculosis in every kidney in which tubercle bacilli were isolated in the urine. He showed me some specimens of resected carcinomas of the rectum together with the lymph nodes from which massive block sections had been made. At Wilkie's surgical seminar a paper was presented by Light, of Toronto, who discussed the increase from .2 per cent in 1931 to .9 per cent in 1936 of pulmonary embolism in Toronto. Forty per cent of all patients with postoperative pulmonary embolism had had, and 12 per cent of all operations had been done under spinal anesthesia. A surprisingly high percentage with pulmonary embolism had had no operation but had succumbed to this condition while lying in the medical wards. He discussed the significance of the recent adoption of Gatch beds in the hospital, which, by virtue of making the patient more comfortable, made it less necessary for him to move about in bed. There was also an interesting paper by Engel, a German refugee, who is working on the permeation of dyes through synovial membranes of joint surfaces. He demonstrated that acid dyes permeate the joint because of their smaller molecular structure and lipoid solubility. Basic dyes do not come through because they are lipoid-insoluble.

Intratracheal anesthesia is very popular in Scotland. Anesthesia in the British Isles is always administered by a physician anesthetist.

In Aberdeen, Professor James Learmouth, formerly of the Mayo Clinic, was very much interested to know what was going on in Minnesota. His associates, Mr. Anderson and Mr. Smith, are in charge of surgical services in the New Aberdeen Infirmary. I had the opportunity to see several cases of intestinal obstruction and to set up an apparatus for decompression of the bowel by nasal suction siphonage. Professor Young, of Marshall College in Aberdeen, is very much interested in pressure changes in osteogenic sarcomas and believes in surgical decompression of the bone to prevent distant metastasis. In the wards of the Aberdeen Infirmary, there were several cases of fractured patella in which the entire patella had been removed with apparently good results.

In Glasgow, Professor Archibald Young, chief of surgery at the Western Infirmary, had been nailing fractures of the neck of the femur since 1924. He reduces many fractures by the open method, and, although he is quite liberal in the use of internal fixation with metal appliances of all sorts, he does not favor any type of skeletal traction.

France

The French surgeon works without the aid of a scrub nurse or an extra assistant and does quite well, despite what would appear to us to be great handicaps. The charity hospitals of Paris are very poor; the wards are crowded. Most of the hospitals in France are run by the State, which spends too large a proportion of its income on armaments to permit very elaborate hospital facilities. The latter is likewise true of Germany and Italy. Only in France are Reverdin needles used. Spinal anesthesia by the Jones method with percain 1-1500 is the anesthesia of choice. General anesthesia is usually induced with ethyl chloride. In amputation for diabetic gangrene the stump is left open with skin traction on the flaps. Healing is not delayed and complications are avoided. Leibovicei, in Cosset's Salpetriere Clinic, is doing one stage abdomino-perineal excision for carcinoma of the rectum, leaving the patient with a sacral (perineal) anus.

In Strassbourg, Professor Fontaine, at the Leriche Clinic, is producing hypertension in dogs by resection of the carotid sinus and a portion of the vagus nerve. For the first time, I saw suction cups applied to the chest in postoperative respiratory complications. Several cases of asthma were relieved by injections of the stellate ganglion with novocaine. Sympathectomy was almost a routine procedure in all cases of Buerger's disease and often was a preliminary procedure in amputations for diabetic gangrene. The anterior approach for the removal of the stellate ganglion is still preferred.

Holland

The hospital of the University of Leyden is organized much like the University Hospitals are here. The chief of the surgical service is Professor Suermondt. Subtotal resections of the stomach for peptic ulcer are done with only a 3 per cent mortality. Cases of very painful arthritis of the hip joint are treated by section of the obturator nerve or by spraying the nerve repeatedly with ethyl chloride. Varicectomy is still being done for varicose veins. Injection of varicose veins is not carried out in this clinic. For cardiospasm, an operation similar to the Ramstedt-Fredet procedure in hypertrophic pyloric stenosis is done, cutting the muscle fibers down to the mucosa of the esophagus and stomach.

At the Hague, Professor Michaels has replaced Professor Jans Schoenmaker, who is now retired.

Professor Nordenbros is in charge of the surgical department of the new Wilhelmina Hospital in Amsterdam. He is using the fibula for fusion osteosynthesis of fractures of the neck of the femur and for bone grafts elsewhere. The treatment of appendicitis there is much like that in our own University Hospitals. In fact, he is one of the few in Europe who advocates conservative treatment of perforated appendictis with peritonitis.

Sweden

The largest clinics in Sweden are located in Lund, Stockholm, Uppsala and Göteberg. These University clinics are among the most progressive in Europe. They are financed by the government and seem to have sufficient funds for research and new equipment. State medicine is well organized in Sweden. Most of the doctors are apparently well satisfied with the system. Everyone is eligible for care at the county and municipal state hospitals at the cost of less than $1.50 a day. The physicians are paid by the state and may, of course, have private practices.

At the University of Lund, Professor Petren is in charge of a surgical division of 225 beds. The hospital was built in 1888 and has had several new additions. A new unit is now being added by the government. Professor Petren has not been won over to the Johannson method for fractures of the neck of the femur, preferring to treat them by a Whitman cast or skeletal traction. Here, I saw a child, eight years of age, with acute cholecystitis with stones. In the southern part of Sweden, there is a very definite goiter belt which is similar to our Great

Lakes region. Osteomyelitis is a very rare occurrence in this part of Sweden.

Professor Sven Johannson in Göteberg was kind enough to demonstrate his operation for internal fixation of fractures of the neck of the femur and allowed me to make some motion pictures of the procedure. Postoperatively, his patients are kept in a semi-Trendelberg position for a week to minimize the danger of thrombosis. Amputated stumps are left open in cases of diabetic gangrene. He showed a case in which he had made a serviceable thumb for a boy by implanting a tibial bone graft into the first metacarpal and covering it with a pedicle graft from the abdominal wall. Like Leriche, he advocates peri-articular injections of novocaine to facilitate early active motion in fractures involving joints. Several cases of advanced carcinoma were being treated with fever therapy.

The Radiumhemmet, in Stockholm, is headed by Professor Berven, who visited here in 1933. The institution was formally opened in October, 1937, and has 130 beds for cancer patients only. It is supported by the King Gustav Fund of 5,000,000 kronen. There is available eleven grams of radium; five grams are in one bomb, three grams in another, and three grams are utilized for radium needles, etc. There are eight new machines of 200,000 voltage for deep x-ray therapy. Next to the Memorial Hospital, in New York City, the Radiumhemmet has more radium than any other cancer institute. Until two years ago, all patients receiving radium therapy had to be treated at the Radiumhemmet. Since then two similar but smaller radium institutions have been established, one at the University of Lund and the other in Göteberg. At the Radiumhemmet there are separate buildings for the study of the physical and the chemical properties of radium. Carcinoma of the tongue and mouth are being treated with teleradium. Fifty per cent of all cases of cancer of the mouth, pharynx and larynx seen at the Radiumhemmet are in young women. Swedish medical authorities associate this with the fact that simple achlorhydric anemia or "Plummer Vinson syndrome" is common in Sweden. Pipe smoking, which is very common among Swedish women, may also be a factor.

Professor Einar Key, "Dean of Swedish surgery," is now retired, his position being filled by Professor John Hellstrom. Professor Key is in private practice and is supervising the building of the new Karolina hospital in Stockholm. Professor Hellstrom, at the Maria Hospital, is doing much urology, although he is chief of general surgery. He demonstrated a patient ninety-one years of age, in whom he had nailed a fracture of the neck of the femur. To facilitate the taking of blood, he is giving donors for transfusion small doses of Heparin. Papaverine is used intravenously to relieve both renal and gallbladder colic, and is kept on the wards for emergency use in cases of pulmonary embolism. Professor Olivecrona of Stockholm is the dean of neurosurgeons in Europe. Most of the younger men who are doing neurosurgery at the various clinics have been trained by him. Professor Nystrom, at the University of Uppsala, is using a new, light-weight type of paper-glue cast, designed by Hulten, to immobilize fractures.

Germany

The operating rooms in the average German hospital are larger than our own. There are three or four operating tables in each room. Septic cases are strictly isolated and are usually operated upon in another part of the hospital. On the whole, asepsis is not carried out to the degree to which we are familiar. In many places neither caps nor masks are worn. If masks are used, they are of poor texture and material and are worn over the mouth alone.

At the Charité Hospital in Berlin, I visited in Sauerbruch's Clinic. Unfortunately, there was no opportunity to witness any chest surgery. While the assistants were properly attired with masks, caps, and gloves of "bona" rubber, the professor disdained these encumbrances. Eighteen cases of inoperable cancer of the rectum were reported cured (1934-1938) by Choual, the radiologist in Sauerbruch's Clinic. The growth is exposed posteriorly through an incision and heavy doses of x-ray are applied directly to the tumor.

In Hamburg, I spent several days at the Eppendorfer Krankenhaus with Professor Konjetzny. The clinic is one of the oldest hospitals in Germany, built on the pavilion system in 1850. Konjetzny is probably more conservative regarding resection of the stomach for duodenal ulcer than anyone else on the continent.

Professor Löhr in Magdeburg has a surgical service of 300 beds in a 1500-bed hospital. He trust only "in God and cod liver oil," and has done more to popularize the treatment with cod liver oil for burns and infections of all sorts than anyone else. Professor Löhr's operation for chronic osteomyelitis is as follows: The infected bone is removed, the cavity is saucerized and irrigated with saline solution to remove all bony particles, and then filled with 30 per cent cod liver oil ointment; no packing of any kind is left in the wound. The skin is closed loosely with interrupted silk suture. Zinc paste and cod liver oil ointment is spread over the skin and a cast is applied and left on for three or four weeks. The cast is bivalved as swelling usually follows such a procedure. In cases of acute osteomyelitis, he incises the periosteum only, fills the wound with cod liver oil ointment and puts on a circular plaster cast. The cast in the acute cases is not bivalved as swelling which usually is present decreases. Professor Löhr claims that 75 per cent of cases of acute osteomyelitis treated in this manner heal without sequestrum formation. If sequestra do form, the usual radical operation for chronic osteomyelitis is done after eight to twelve weeks. Large doses of cod liver oil are given by mouth in the treatment of peptic ulcer. He claims that the ulcer heals like any other wound (bathed in cod liver oil). Incidentally, the patients are kept in bed. He is also injecting a purified form of cod liver oil into arthritic joints claiming that it relieves pain. Several cases of ununited fractures of the tibia were treated by Beck's multiple drill method with resection of a piece of fibula. Arteriograms of the brain are made by puncture of the internal carotid artery. Professor Löhr demands clearer indications for gastric resection in cases of peptic ulcer than previously, and states that in the northern part of Germany there is a general swing toward conservatism in the management of peptic ulcer.

In Leipzig, Professor Willy Rieder has succeeded Payr as chief of the largest surgical clinic in Germany. Rieder is one of the youngest and most progressive chiefs of clinics in the Reich and is very cordial to visitors. The fracture service is very large and patterned after that of Boehler's in Vienna. Rieder is an excellent operator. A carcinoma of the gallbladder was resected together with a portion of the liver. He anchors the peritoneum to the skin edges to protect the wound from contamination. All laparotomy wounds are covered with an electric light cradle lamp instead of dressings. Buerger's disease is treated by sympathectomy. Thirty-three cases of ten-year follow-up were presented; 40 per cent of these were back at work.

Professor Georg Magnus has come to Munich from Berlin to succeed Lexer who has recently died. He is in disagreement with Boehler regarding the treatment of fractures generally and especially of fractures of the spine. He prefers to have his patients lie in bed without reduction for six weeks and then to get them up without braces. He claims good results in a high percentage of cases. Fractures of the neck of the femur are treated by wire traction reduction only.

The new surgical hospital in Tübingen is one of the most modern hospitals in Germany. It was completed five years ago under the supervision of Professor Kirschner who is now in Heidelberg. At Tübingen, Professor Kirschner has been succeeded by his pupil, Professor Willie Usadel, who demonstrated Kirschner's method of spinal anesthesia in which spinal fluid is replaced by air. He also showed Professor Kirschner's apparatus for local anesthesia by pressure infiltration. Professor Usadel is enthusiastic about getting patients up immediately after operation and advocates setting-up exercises in bed beginning the second postoperative day. He has gone back to the two stage procedure for the removal of carcinoma of the rectum. Professor Usadel is of the opinion that antiserum is of definite value in appendiceal peritonitis. He uses a light weight steel support to re-inforce plaster spica casts. For Buerger's disease, he gives a papaverine preparation intravenously, and follows this with sympathectomy.

At Heidelberg, I found that Professor Kirschner was in Berlin on military duty. A new hospital being built for him by the government is still not complete. Kirschner's operation for perineal prostatectomy and his procedure of fulguration of the Gasserian ganglion for trigeminal neuralgia were demonstrated by his Ober-Artz. The Gasserian ganglion has been fulgurated in over 300 cases of neuralgia with satisfactory results. The apparatus for x-ray control of this procedure has been developed to a fine degree.

Austria

I think that asepsis in Professor Wolfgang Denk's Clinic in Vienna is superior to that in any central European clinic. Professor Denk uses muscle tone tests as an index of the patient's general resistance and of his ability to withstand a major operation. There has been no diminution in the number of gastric resections done in Viennese clinics for peptic ulcer. In gastric resections for carcinoma, all of the greater omentum is removed together with the lesion. Felsenreich, in charge of fractures in Denk's clinic, is especially interested in osteosynthesis in fractures of the neck of the femur. The nail he uses is somewhat larger than the Smith-Peterson nail. He has had some excellent results and has summarized his cases in a recent book.

Professor Finsterer, who is still very active, does gastric resection even in cases of bleeding duodenal ulcer. He has resected sixty-four such cases with only four deaths. These deaths were from pneumonia. In young individuals, he prefers the Haberer type of subtotal resection and thus removes less of the stomach. He has had one death in a series of thirty-three cases of perforated peptic ulcer in which he did subtotal gastric resection. He has a total of twenty-one cases of total gastric resection. Five of his cases are still alive. He resects carcinoma of the rectum in one stage and states that he has done 210 cases in which he has been able to preserve the sphincter. The rectal sphincter is preserved in 60 to 70 per cent of his cases by a one stage operation with anastomosis of the proximal colon to the rectum just above the sphincter

Boehler, at the Unfall Krankenhaus, is an enthusiast over complete immobilization for infections and treats even potentially infected wounds by immobilization in plaster casts—methods which have been in use at our University hospitals for some years. He treats fractures of the shaft of the femur by skeletal wire traction through the tibial tuberosity for four weeks, and then skin traction of the thigh and leg by means of Unna's paste bandage traction. He is most impressive in his treatment for compression fractures of the spine. These fractures are reduced immediately under local anesthesia by forceful reduction and then a nonpadded plaster body cast is applied. In cases with paralysis, he reduces the fracture and says he has found it unnecessary to do laminectomy. The duration of fixation depends on the angle of the deformity of the fracture line. If there has been a 12° deviation, the plaster is left on for twelve weeks, if 20°, the plaster is left on for twenty weeks. The plaster applied is always nonpadded. Patients are allowed to be up and about immediately and started on active exercise. He always has a half dozen cases on hand who go through a regular circus type of exercise doing acrobatic stunts which patients with normal backs could not perform. Boehler is definitely opposed to any form of physiotherapy such as baking and massage and says this type of treatment promotes bone atrophy, skin discoloration and stiffness of the joints. He is a firm advocate of active motion only. He uses no type of gas or tetanus antiserum and has seen only one death from gas gangrene in 5,000 cases of compound injuries. This one death followed injury of the popliteal artery. He has had four cases of tetanus in 40,000 cases of injury with only one death.

In Budapest, Hungary, Professor Novak presented ten cases of esophagoplasty which he had done for stricture of the esophagus following burns. He first does a Witzel gastrostomy and four to six months later implants the distal end of a loop of the jejunum into the stomach and the proximal end into the abdominal wall in the epigastrium. Then the esophagus is sectioned and brought out to the left side of the neck and eventually a skin flap tube is made to connect both fistulas.

Switzerland

In Basel x-ray therapy is advocated by Professor Henschen for all types of infections. Routine x-ray therapy (1/5 skin unit) is recommended as prophylaxis for thrombophlebitis. In Professor DeQuervain's clinic in Berne, prophylaxis against thrombophlebitis is attempted by injection of a solution of Heparin into the wound. For hemostasis in hemophilia, an extract of thyroid tissue (colloid goiter) is being injected. Another hemostatic, manetol (Bayer), is an extract of nerve tissue of the brain and spinal cord of the guinea pig. In Zurich, progynon is being used in the treatment of Buerger's disease by Clairmont. DeQuervain is now at retirement age and will be succeeded by Mattis.

Italy

Putti's Clinic is situated high on a hill overlooking Bologna and is one of the oldest hospitals in Europe. It has been modernized recently and has beautiful wards and ultra-modern equipment. With new technique, x-rays are developed within seventeen seconds in the operating room, obviating the need of fluroscopy. The Italian officers who sustained wounds of the bones and joints in the Ethiopian and Spanish wars are cared for in this clinic.

I visited Professor Ascoli, surgical director of the Forlanini Institute in Rome. This new institute, recently built by Mussolini, has 1,400 beds for the treatment of tuberculosis; the surgical division has over 200 beds. Every visitor is proudly escorted through the entire building, which is one of the most modern institutes in all Italy. Professor Ascoli advocates anterolateral thoracoplasty, doing a phrenic exeresis with resection of the fourth, fifth and sixth ribs through a lateral approach. Two weeks later the upper stage is done through an upper axillary incision.

Comment

Anyone who has had the necessary fundamental training and preferably a certain amount of postgraduate experience, cannot fail to gain a great deal from a visit to foreign surgical clinics. I would recommend, however, that most of the time be spent in the British Isles and in the Scandinavian countries. There the friendly reception and hospitality is better than it is in central Europe which has been over-run in the past by those seeking postgraduate training. The language difficulties which beset the average traveller are also less bothersome in northern Europe. English is taught throughout the Scandinavian countries and is spoken in all of the clinics. It is my impression that clinical and experimental research in the British Isles and the Scandinavian countries is now on a higher level than that in the rest of Europe. Nowhere, however, is such a vast amount of work being carried out as in our own universities and large clinics. A brief sojourn of a week or ten days in each clinic is to be preferred to a longer stay in any single place. This is particularly true if the traveller has had sufficient postgraduate training or experience to be able to evaluate the differences in methods and personalities of the various men visited.

Although the keen observer will note much of value to him he will also disapprove of many procedures as he sees them carried out abroad. He should, however, refrain from too critical comparisons. He will come to appreciate, I am sure, our own advanced status in equipment, methods and asepsis, and will realize how valuable and important it is to be free from the political interference that the medical profession is forced to endure throughout most of Europe.

INDICATIONS FOR CESAREAN SECTION*

RUSSELL J. MOE, M.D.
Duluth, Minnesota

DUE to perfection of surgical technic during the past few decades there has developed a false sense of security in the cesarean section operation. The indications have been widened to keep pace with this progress in surgical development to the point where almost any obstetrical complication which is not readily corrected becomes in some parts of the country an indication for an abdominal section. Williams and Stander, as well as many other writers, are of the opinion that there are too many cesarean sections performed for insufficient indications. An operation which carries a mortality of 4.1 per cent, as shown by Lynch in a recent survey, must be given due consideration and rigid limitations. The fact that the mortality in the hands of experts is as low as any abdominal operation does not justify the operation without a very definite indication.

---

*Read before the Northern Minnesota Medical Association, Crookston, Minnesota, August 29, 1938.

The indications for cesarean section are considered as absolute or relative. The absolute indication is one in which a living fetus cannot be delivered through the birth canal, while the relative indication is one in which the fetus may be delivered through the birth canal, but its chances of survival, as well as that of its mother, are increased when cesarean section is performed.

Disproportion

A contracted or a deformed pelvis, in which either the inlet or the outlet is so small as to prevent the delivery through the birth canal, is an absolute indication for cesarean section. There is much variation in the size of pelves, as well as in the size of passengers, and therefore one must exercise judgment in determining whether or not delivery is possible through the birth canal. A patient with a justo minor pelvis and a large baby may be a candidate for a section, while it is probable that a small baby would deliver normally through the same pelvis. The simple process of determining the pelvic measurements and the size of the fetal head will usually indicate whether or not cesarean section is necessary. The cases of disproportion in which the indication is not definite should all have a real test of labor before abdominal delivery is decided upon.

Hemorrhagic States

This group of indications is composed of conditions in which the blood loss may be great, thereby increasing the hazard for both mother and child. They are usually emergency conditions and demand immediate treatment. Placenta previa is an indication when the hemorrhage is severe and the condition of the cervix is such that the bleeding cannot be readily controlled or the delivery completed rapidly from below. Various groups of statistics show conclusively that the maternal and fetal mortality are reduced when cases of placenta previa with severe hemorrhage and undilated cervix are treated by cesarean section. Placenta previa, abruptio placentæ or a ruptured uterus may bleed so severely as to indicate abdominal delivery in spite of the fact that the fetus is dead. The latter two conditions also sometimes require the removal of the uterus.

Obstructing Lesions

Among the obstructions to the birth canal which may indicate an operative delivery through the abdomen are fibroids in the lower uterine segment, ovarian cysts or dermoids, previous surgical procedures, carcinoma of the cervix, rigid cervix and acute edema of the vulva. One is often surprised, however, at the change in the position of a fibroid during the first stage of labor as the lower uterine segment is pulled upward over the presenting part. Previous surgical procedures, such as high amputation of the cervix and certain fixation operations of the uterus, may contraindicate normal delivery. In elderly nullipara one occasionally encounters a rigid cervix which will not thin out or dilate readily. While there is much difference of opinion as to the procedure to be followed, most obstetricians are agreed that a test of labor should be allowed and continued as long as there are no indications of maternal or fetal distress. Many of these patients will deliver normally if given a chance. Mengert reports that in nine and a half years' experience at the University of Iowa there was not a single instance in which rigid cervix was given as an indication for cesarean section. It is important in these cases to conduct the labor in such a manner that an abdominal hysterotomy does not become contraindicated.

Previous Distocia

A patient with a history of two or three previous difficult labors, ending in death of the fetus, may well be a candidate for cesarean section, and it is best performed at the time of election. The x-ray study of the bony pelvis may be expected to give more information in some of these cases in the future.

Previous Cesarean Sections

"Once a cesarean always a cesarean" is not true unless the operation has been performed for an absolute indication. The previous indication may not be present during a subsequent pregnancy. If the puerperium following the section was afebrile, and there is every reason to believe there was good healing of the uterine wound, the patient may be allowed to go into labor, but should be watched closely in a hospital and immediate operation carried out if weakness or rupture of the uterine scar becomes apparent. However, elderly nulliparas, in whom previous myomectomies have been performed, should not be allowed to go into labor. They are more apt to have a ruptured uterus than a patient with a previous section.

Malpositions

Abnormal positions of the fetus or the presenting part occasionally indicate interference in the way of abdominal delivery. Transverse positions, brow and face presentations, often cause a difficult prolonged labor, with considerable danger to the child. Each case must be judged on its own merits, but fundamental knowledge and skill in obstetrical procedures will overcome or correct many of these malpositions without resorting to radical operative measures.

Medical Complications

Heart disease and tuberculosis are very rarely justifiable indications for cesarean section. Proper treatment, with the assistance of a competent internist, during the pregnancy, is of primary importance. Forceps delivery, as soon as dilatation is complete, will conserve the patient's energy by avoiding the expulsive effort during the second stage of labor.

Before the use of insulin it was common knowledge that the fertility of diabetic women was low. At the present time, however, we are seeing more diabetic mothers going through pregnancy, and it has presented a problem which is not yet generally recognized. Diabetic mothers are known to have a high fetal death rate. The babies are practically always much overweight, predisposing to a difficult and prolonged labor, during which they often succumb. Priscilla White, Randall and Rynearson recommend the premature delivery of the infant of the diabetic mother by cesarean section during the thirty-sixth or thirty-seventh week of pregnancy. The immediate care of the infant is also very important, to prevent postpartum death from hypoglycemia.

Rarely severe nervous disorders may be considered as indications for abdominal section, especially where the labor may place an undue strain upon the mother.

Toxemia

Eclampsia is not an indication for cesarean section. Eclamptic patients do not tolerate shock, and statistics have proven repeatedly that better results are obtained by conservative measures. Non-convulsive toxemias which do not respond to known measures of treatment and are fulminating in character may be considered as proper indications, and are best performed under local anesthesia.

The accompanying table is a résumé of the indications for cesarean section performed in St. Luke's and St. Mary's Hospitals in Duluth during the seven-year period from 1931 to 1937 inclusive.

TABLE I

	Number	Per cent
Number of hospital deliveries	8,736	
Number of cesarean sections	95	1.08
*Mortality following cesarean sections	1	1.05
Indications		
1. Disproportion		
Contracted pelves	22	23.1
2. Hemorrhagic States		
Placenta previa	13	13.65
Abruptio placentæ	7	7.35
Ruptured uterus	2	2.1
3. Previous Section	13	13.65
4. Previous Dystocia	10	10.5
5. Toxemia	8	8.4
6. Obstructing Lesions		
Tumors	4	4.2
Elderly nullipara	2	2.1
Previous high cervical amputation	1	1.05
Acute edema of vulva	1	1.05
7. Malpositions		
Transverse	3	3.15
Brow	1	1.05
Face	1	1.05
8. Dystocia	3	3.15
9. Medical Complications		
Heart disease	3	3.15
Severe Parkinsonian	1	1.05

---

*The one death was due to a ruptured uterus following soon after operation.

Conclusions

1. A plea is made for more conservatism and more definite and rigid indications for the performance of cesarean section.

2. It is important to conduct a labor in such a manner that an abdominal operation does not become contraindicated.

3. Sins of omission are still adding to the maternal and infant mortality in the treatment of placenta previa and diabetes.

4. A fundamental knowledge of obstetrics and skill in obstetrical management will obviate many of the questionable indications for cesarean section.

5. A brief résumé of the indications for

cesarean section performed in Duluth for a seven-year period is presented.

PROGESTERONE IN THE TREATMENT OF HABITUAL ABORTION*

S. B. PETERS, M.D.

Silver Creek, New York†

THE use of progesterone or corpus luteum containing extracts in the treatment of habitual abortion has a definite experimental foundation. It is too true, we all must agree, that the theoretical concepts of gynecologic endocrinology, when applied clinically, have proved very disappointing. There have been many optimistic claims advanced as to the values of hormones in the treatment of numerous disorders of the female genital tract, but few have met the test of clinical application. Many or most of them have failed dismally. However, in the past few years there have been certain and definite advances in the field that even the more conservative gynecologists are coming to recognize.

We have but to review the work of Corner[3] and of Corner and Allen[4] at the University of Rochester to become convinced of the necessity of the presence of corpus luteum extracts or the chemically pure hormone itself to maintain pregnancy in the rabbit. In the human being the corpus luteum of the ovary remains active until the fourth month of gestation, when it begins to degenerate slowly, until about the sixth or seventh month, when usually there remains little or no evidence of its presence. We know that the ovary containing the corpus luteum of pregnancy may be removed after the fourth month of pregnancy with only a small chance of abortion or premature labor following. It is thought that the placenta takes over the manufacture during the remainder of the pregnancy.

We are indebted to the work of Fraenckel[8] in 1903, for the foundation of an important series of advances. He demonstrated that the removal of the corpus luteum of the rabbit resulted in absorption or premature expulsion of the fetus. Allen and Corner[1] conclusively proved that progesterone is necessary for the conservation of early pregnancy. Knaus[10] and Manzi[12] showed that progestin maintains the uterus in a state of quiescence during pregnancy and that the uterus becomes sensitive to preparations of the posterior lobe of the pituitary when the influence of the corpus lutem declines. Hisaw[7] demonstrated the ability of progestin to nullify the effect of posterior pituitary extract. Estrogenic substance, on the other hand, sensitizes the uterus to the oxytocic principle of the pituitary, thus stimulating uterine contractions. Abortions have been produced in animals with excessive doses of estrogenic material. The method by which the estrogenic substance sensitizes the uterus to the oxytocic principle of the posterior lobe of the hypophysis is not clear. It is debatable whether it stimulates an increased production of the hormone.

Pratt[13] has shown that there is less than one international unit of progesterone in 40 grams of human corpus luteum and Bloch[2] has shown that there is less than one unit in each of eight and twelve liters of sow's blood. These observations are interpreted to mean that production, utilization, and excretion are continuous and that there is little storage. More recently Venning and Browne,[14] et al, at McGill, have formulated a method for quantitative determination of a substance, pregnandiol-glucuronidate, in human urine. Measurements of the excretion of this substance have been made during the normal menstrual cycle and throughout pregnancy. This product is considered to be an excretion product of progesterone. They find from a short series of normal menstruating women that this product, pregnandiol-glucuronidate, is not excreted during the follicular phase of the cycle (the first fourteen days of a twenty-eight day cycle), but only in the luteal phase of the cycle. The time of onset of menstruation in their cases bears a definite relationship to the disappearance of this substance from the urine. That time is consistently two or three days. The presence of this substance does then correspond to the activity of the corpus luteum and further substantiates Pratt's conclusion that production, utilization and excretion are continuous.

---

*Read before the Northern Minnesota Medical Association, Crookston, Minnesota, August 29, 1938.

†The author formerly lived in Virginia, Minnesota.

Venning and Brown[14] further find that during pregnancy the urinary output of pregnandiol-glucuronidate shows a definite increase usually beginning in the third or early in the fourth month and this output continues to rise from then until the eighth or ninth month. Within twenty-four hours of delivery the compound disappears practically completely from the urine. Patients who have a tendency to abort have a lower output than in the cases of normal pregnancy studied. These observations are certainly in accordance with the principles set forth heretofore that this substance, pregnandiol-glucuronidate, is an excretion product of corpus luteum, that its precursor, the hormone corpus luteum, is not stored, that its production and utilization is parallel and equal, and that its lack would produce spontaneous abortion or premature labor. Substitutional therapy with the corpus luteum hormone or chemically pure progesterone should then seem indicated in cases of habitual abortion.

I have had occasion in the past year to treat four cases of recurrent spontaneous abortion and carry them to term with delivery of normal living infants. I will report these cases. The general method of treatment followed was the biweekly intramuscular injection of progesterone or corpus luteum extracts amounting to approximately one international unit, as soon as the diagnosis of pregnancy was made and up to and including the fifth month of pregnancy. There was one exception to this procedure which will be discussed in turn. In all cases the blood Wassermann reactions were negative and nothing in the history, physical examination or laboratory data could be found to account for the abortions.

Case No. 1.—A thirty-nine year old para 1, gravida 4, whose first pregnancy terminated in a full term low forceps delivery of an 8½ pound living normal male. The second pregnancy terminated spontaneously near the end of the third month, as did the third pregnancy. The last menstrual period was March 6 and estimated date of confinement was December 13. This pregnancy, as were her previous pregnancies, was characterized by severe nausea and vomiting in the early months. The general physical examination was entirely negative, as were the laboratory examinations of the blood and urine. The blood Wassermann was negative. The patient was first seen when eight weeks pregnant. Three-tenths grain of the soluble extract of corpus luteum was given intramuscularly for the next three days with very marked improvement in the nausea and vomiting and the same dosage was given twice weekly for the subsequent eight weeks. The remainder of the prenatal period was uneventful, and the patient was delivered of an 8.5 pound living normal female infant, also by low forceps.

Case No. 2.—A thirty-three year old para 1, gravida 5, whose first pregnancy terminated in a full term normal delivery in 1931. Her next three, pregnancies terminated at four, three and three months respectively, by spontaneous abortions. The last menstrual period was July 27, 1937, and the estimated date of confinement was May 4, 1938. This patient, like the first patient, complained of severe nausea and vomiting in the early months. There were also associated flashes and severe headaches. Two years previously she had undergone an operation for an ovarian cystadenoma and the left ovary was said to have been removed. Her previous menstrual history was normal. The general physical examination was essentially negative except for a well healed midline suprapubic operative scar. The blood and urine studies, as was the blood Wassermann, were negative. The patient was first seen when she was seven weeks pregnant and one international unit of progesterone was given intramuscularly and repeated every other day for three doses. Then the same amount was given biweekly over a period of ten weeks, which corresponded to her fourteenth week of pregnancy. This patient also responded quite spectacularly in regard to the disappearance of her nausea and vomiting and associated symptoms. These difficulties were cleared up almost entirely after the third injection. The remainder of her pregnancy was uneventful, and she was delivered of a 7.5 pound normal female infant, May 1, 1938.

Case No. 3.—A twenty-three year old para 0, gravida 3, whose first pregnancy terminated at the end of the third month at the time she would have menstruated normally. Her second pregnancy terminated spontaneously two years ago at the end of the third month, also when she would have normally menstruated. The last menstrual period for her third pregnancy was July 22, her expected date of confinement was April 29. I first saw her on a home call, at which time she complained of spotting. This was about nine weeks after her last menstrual period. She was placed on bed rest and given one international unit of progesterone for two successive days. She was then given the same dose two times weekly for the next six weeks. Her previous menstrual history was normal. Her general physical examination was negative, as were the blood and urine studies. The remainder of the pregnancy was uneventful with exception of the development of varicose veins in the legs, which were injected and responded well to treatment. She was delivered of a normal female infant on April 25, 1938.

Case No. 4.—A twenty-three year old para 0, gravida 4, whose first pregnancy terminated at five months in premature labor with a stillborn infant; second pregnancy terminated at seven months with premature labor and a stillborn infant; third pregnancy terminated at six months with premature labor and a stillborn infant. There was nothing in her history to suggest diabetes, lues or hypothyroidism. The blood Wassermann had been negative on three previous occasions. Her previous menstrual history was regular and normal. Her last menstrual period was October 18, and her estimated date of confinement was July 25. Her general health appeared excellent. The general physical examination was essentially negative, as were the blood and urine studies. Basal metabolic rate done when first seen at 6 weeks following her last period was plus 5 per cent. The blood Wassermann was negative. Progesterone, one international unit, was given intramuscularly every two weeks from the eighth week to the fourteenth week, then once weekly from the fourteenth to the 36th week. Iron medication, high vitamin diet and general hygienic measures were instituted early in pregnancy and maintained throughout.

The entire prenatal period was uneventful and the patient had a spontaneous labor and was delivered of a normal living 7.5 pound female infant July 24, one day from the estimated date.

Other cases in the literature are as follows: Krohn, Falls and Lackner[11] reported eight cases of habitual abortion in a series with threatened abortion in which was given 1 international unit of progesterone weekly up through the thirty-second week and each was terminated successfully at term. Kane[9] reported forty cases; ten had one living child each and then had aborted one to three pregnancies subsequently; twenty had had one previous abortion, fourteen had had two, four had had three, one had had four, and one had had six previous abortions. Out of this group there were but four failures; one pregnancy ended at six months. In another a two-month fetus was expelled after five months of pregnancy and there was one abortion at two months and one at three months. Prolution (Schering) was used in his patients as follows: 1/25 international unit was given every other day for ten doses. This was repeated at three-week intervals up to the thirty-second week. His patients received at the most just two international units of the hormone. In addition each patient received one-half grain of desiccated thyroid three times daily for four weeks and four grains of sodium iodide three times daily for two weeks following the thyroid medication. All medication was stopped at six months. In his series of forty, Kane noted a definite increase in fetal abnormalities. Elden[5] reported a series of eight cases in which treatment was carried over a period of six lunar months and from ten to forty-four international units progesterone were used. Six of his cases were successful; two were failures. Of the six successes five had had at least three to five abortions and had carried none to term. One had had one living child, her first pregnancy, and three subsequent abortions. One failure was attributed to a Dudley operation on the cervix and occurred at the end of the fourth month, and the other had terminated in a premature labor at seven months, treatment having been stopped three months previously.

The causes of habitual abortion are many and varied. The lack of the hormone produced by the corpus luteum is but one—chemic systemic disease, syphilis, nephritis, hypovitaminosis, hypothyroidism, defective decidual reaction and fetal malformation being a few of the other causes.

It is reasonable to suppose that abortion would have occurred in some of the patients reported above if treatment had not been instituted. The dosage at present is empirical. Kane used but two international units over a period of thirty-two weeks. Others have used almost as much as fifty international units. Elden and Wilson[6] have shown that very minute amounts can be used to control dysmenorrhea in selected cases. It is probable that much smaller doses than we used may prove efficacious.

As to the period of medication it would seem logical, in view of Venning and Brown's very excellent work on the output of pregnandiol-glucuronidate to treat these patients until the eighth month, especially if a history of premature labor exists.

No definite conclusions can be stated from so small a series of cases, even including those reported in the literature, but the speculation can be made that in progesterone we have a specific for a certain type of quite common recurrent abortion and premature labor, a view which is corroborated by experimental studies.

HUMAN HEREDITARY DEFECTS*

E. J. ENGBERG, M.D.

Faribault, Minnesota

By heredity is meant the transmission to individuals of various specific, desirable or undesirable, physical and mental qualities present in parents or more remote ancestors.

It is important to know what conditions appearing to be inherited are truly so, because many earlier ideas were wrong. We now know that syphilis and tuberculosis are not inherited, but are the result of direct infection. Congenital syphilis is the result of infection and not of inheritance even if the effects of the disease are evident at birth.

Harmful effects in the environment may impair the individual's efficiency, and, if sufficiently severe, result in sickness, while the harmful effects of inherited forces result in defects. These defects are numerous and many physicians have not fully recognized the important rôle played by inheritance in causing disabilities or freedom from them in man.

It is surprising that before the knowledge of fertilization, the fundamental laws of inheritance were discovered by experiments conducted and analyzed by Gregor Mendel. His work was published in 1866, but no one grasped its tremendous importance until in 1900, when three botanists working independently demonstrated that his basic laws of heredity are active through the entire plant and animal kingdoms. The first human case was that of a hereditary shortening of fingers and toes, reported in 1905.[2]

Mendel worked with various types of garden peas, but it is easier to cite an experiment in animal life as described by Dr. Otto L. Mohr,[2] Professor of Medicine, at the Royal Fredericks University, Oslo, in his book, "Heredity and Disease." From this book the author, with the kind consent of the publishers, W. W. Norton and Company, Inc., has been permitted to use material for this paper. If we breed a pure-bred black rabbit with a pure-bred white, all the offspring in the first generation will be black. If we breed these black rabbits together, however, we obtain in the next generation both black and white rabbits and these in a fixed ratio of three black and one white. Furthermore, when these white rabbits are bred together, all their offspring are white, but the black if bred together act differently, as one of them is pure-bred black and by inbreeding gives black only, while the other two black are hybrid and by inbreeding give black and white offspring, and again in the ratio of three black and one white. Furthermore, if the hybrid blacks are bred with their white brothers or sisters, they yield equal numbers of white and black.

The explanation for the color present in the various rabbits in the experiment is that each rabbit carries two genes for color. In the pure black, both are for black coloring, while in the

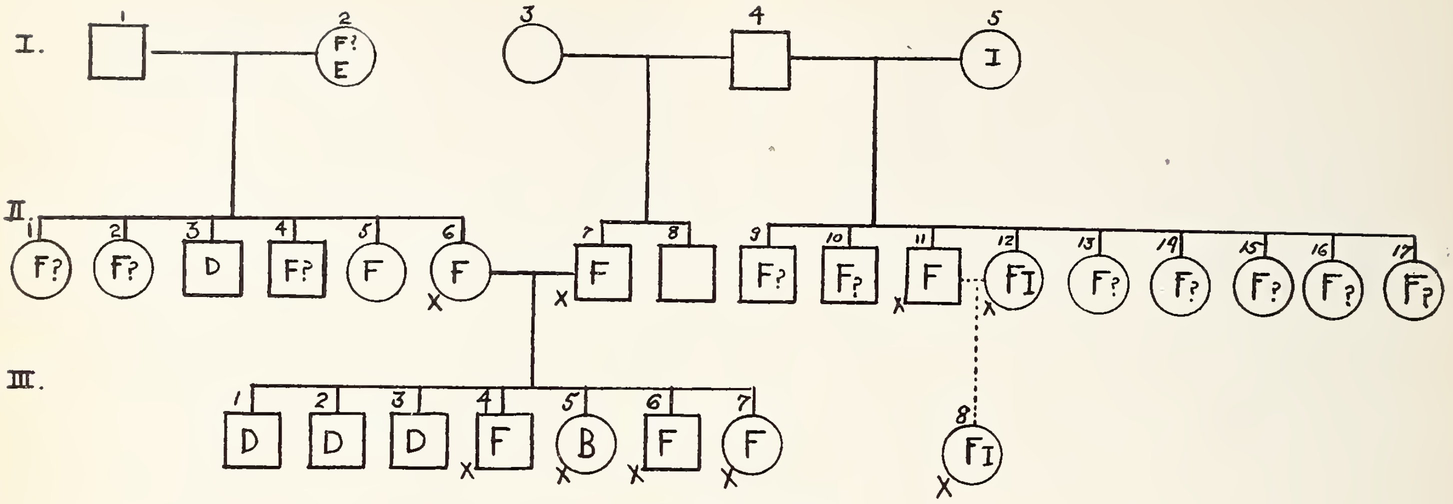
CHART I. THE "B" FAMILY



Prepared in 1933

Explanation of Chart

I, II, III, Generation. Symbols: Male ☐ Female ○

Connecting horizontal line indicates marriage. Vertical descending line indicates offspring.

F—Feeble-minded (Followed by (?) indicates no test, but described as mentally defective.)
B—Borderline
E—Epileptic
I—Insane
X—At some time in the State School for Feeble-Minded.
D—Died in infancy

GENERATION I

1. The maternal grandfather was born about 1839 and was said to be feeble-minded.
2. His wife was described as both feeble-minded and epileptic.
3. The first wife of the paternal grandfather died of brain fever at age thirty-three.
4. The paternal grandfather is described in one record as "mentally fair."
5. The second wife was committed to the Fergus Falls State Hospital in 1887, but must have been released in a short time, as her next child was born in 1888. There is a question of feeble-mindedness here rather than insanity as she is described as "mentally inactive."

GENERATION II

1, 2, and 4 are described as feeble-minded.

3 died at the age of three.

5 is described as an epileptic half-sister so probably there was another mating in the first generation, although there is no information.

6, the mother of the third family, was born in 1875, married in 1903, and had an Intelligence Quotient of 53, which was determined while she was at the School from 1912 to 1915.

7, the father of the third family, was also institutionalized from November, 1912, to November, 1914. He had a mental age of 9 1/5 years in 1912, the I.Q. not being recorded. His birth date was about 1871.

8 has been a farmer all of his life, and has never been tested.

9, 10, 13, 14, 15, 16, 17 have never been committed as feeble-minded, but are declared to be defective in varying degrees.

11 was committed in 1929 and then admitted to the School where he now is. His I.Q. is 55, and he is the father of an illegitimate girl by his sister.

12 was also committed and is now in the institution, I.Q. 47. She is the mother of the girl (Generation III, No. 8) by her brother.

GENERATION III

1, 2, and 3 died in infancy.

4, I.Q. 47, first admitted in 1910. He has been paroled several times, sterilized, and finally readmitted for an indefinite stay.

5 admitted in 1912, and received the training of the School Department. She was paroled in 1924 on account of a borderline test of 84. She maintains herself with help and supervision.

6 tests 71. He has been at Red Wing Training School, and then in the institution for short intervals. After sterilization, he has supported himself partially by manual work and playing the piano for country dances.

7 tests 53, first admitted in 1912, was sterilized, tried on parole, failed to adjust, and is now in the institution.

8, the offspring of the brother and sister mating, was admitted in 1929. Her I.Q. is 38. This girl and her mother have shown a mental deterioration actually amounting to dementia præcox since institutionalization.

Note.—Only the members of the family about whom there is some description in the records at the School are included in the chart. No research has been done in the community where there are many more members who have married and reproduced.

pure white both are for the lack of color or albino state. In the hybrid blacks each has received one gene for black and one for white color, but the black gene being dominant renders the white or recessive gene inactive. The recessive (white) gene can cause the white color only when a mature egg carrying one recessive unit in fertilization combines with another mature germ cell also carrying that particular recessive gene. Therefore, only pure white bred with pure white results constantly in white offspring, as then only recessive genes for color are present in each parent. In the pure black rabbit both genes for color are for black, while in hybrid blacks one gene is for the dominant color black and one for the recessive color white. The inbreeding of the hybrid blacks results in the following combinations of genes: black-black 25 per cent, black-white 50 per cent, white-white 25 per cent. The first 25 per cent carry the gene for black color in two units so that the offspring are pure-bred black, 50 per cent carry one unit for black and one for white, and, as the black gene is dominant, result in these offspring being hybrid black; while 25 per cent carry both genes for white color, resulting in white offspring. Accordingly, an individual may carry a particular gene in double or single dose as determined by the particular inheritance. The germ cells of each parent, however, are genetically pure and will contain any given gene present in the parent in single unit only, uninfluenced by the combination of genes that were present in the parent.

The same rule of inheritance applies with reference to the color of eyes in man. Brown is dominant, blue is recessive, and brown-eyed or blue-eyed individuals are born according to the Mendel formula of inheritance.

The illustrations cited thus far have to do with the transmission to offspring of inherited qualities carried in the genes of the parent germ cells having to do only with color determination. However, all of the various genes present in a given germ cell each carry a specific quality that may be desirable or extremely valuable, or that may be undesirable or even devastating in its effect. These all exert their influence in accordance with biological laws of inheritance in determining the physical and mental characteristics of the offspring, except as they are influenced by environmental factors. A dominant case of defect in man reported by Dr. Mohr[2] is that of finger shortening affecting only the second phalanx of the second fingers and toes in which the dominant inheritance was traced back six generations to a Norwegian woman born in 1764. Of her ten living and seven stillborn children, the family record stated: "Every second child had, as she has herself, a shortened crooked forefinger with one joint only."

Consanguinous marriages favor the appearance in offspring of recessive traits and the defect may not have been apparent for several generations. The data on albinism is very extensive and illustrates this tendency well, as extensive studies have been made showing consanguinity in the production of albinotic children in 50 per cent of one series and 33 per cent in another. Theoretically, such a mating will result in 25 per cent being albinotic, but in human families with a small average number of children, many instances will show no affected children in spite of the theoretical three and one ratio.

Certain inheritance defects are sex-linked. An example of this in man is that of color blindness, in which case vision is normal but the individual cannot distinguish between the colors red and green. Although we shall not discuss the scientific facts in the transmission of this defect, extensive studies show a frequency of 8 per cent color-blind men and 0.5 per cent of color-blind women in the general population. Hemophilia is another sex-linked defect. No established cases of hemophilia in women are known.

Hereditary defects in the organs of special sense are very striking. Hereditary deafness is due to recessive genes; and even the deafness in later life due to otosclerosis seems in a number of cases to be best explained by the presence of a recessive gene carrying this defect. Some of the most striking and most destructive inherited defects are those affecting the eye. Congenital night blindness is one of the best examples of dominant inheritance. Mohr cites one French family in which this defect has been present through ten generations. Of more serious eye lesions are certain cases of glaucoma which may be dominant or recessive sex-linked; a large number of hereditary cases of cataract, mostly dominant but very different in types and in time of onset; and also cases of retinitis pigmentosa.

It is generally agreed that about 50 per cent of the mentally defective are so because of inherited defect. Mongolism is not. Goddard[1] concluded from his extensive studies that normal-mindedness as opposed to feeble-mindedness behaves like a dominant unit character and is transmitted in accordance with Mendel's law. Therefore, when both parents are feeble-minded, there is a distinct tendency for all of their children to be feeble-minded. Investigators have concluded that infantile amaurotic idiocy is due to the effect of a single sublethal recessive gene.

In our institution for mental defectives at Faribault some interesting inheritance studies have been made. Dr. A. C. Rogers, while superintendent, showed this in his very interesting publication "Dwellers in the Vale of Siddem." A chart prepared for the Children's Bureau of the Board of Control in February, 1937, shows the social burden resulting from the intermarriage of the families which are, for the purpose of study, known as "Callerquist" and "Larkeson." As a result of this union, sixteen descendants have been in our institution. Another study made by Miss Caroline Perkins of our Social Service Department of the "B" family (Chart I) showed the same resulting social burden with the particularly interesting fact that, as a result of the union of two feeble-minded individuals, three children were dead and their mental state undetermined, while the other four children and the parents were inmates of our institution. Dr. A. R. T. Wylie, of our medical staff, kindly prepared for use in this paper a list of families with several members now in our institution. In one instance, we have eleven members and have had sixteen; in another instance, fourteen; and in five instances, four members of each family are still in the institution. One of these families consists of the father, mother, and two children. In another case, we have had four and still have two remaining. The other two have died in the institution. In still another case we have five of the same family; and in two instances, six of the same family. Finally, we have one family of eight, including father, mother, two sons and four daughters.

The exact status of inheritance in the psychoses is not clear except that one considers, as do the English particularly, that the defect is one which may show varying psychoneurotic states such as psychoses, feeble-mindedness, epilepsy, migraine, et cetera. However, inheritance has been shown to be of a great deal of importance in the etiology of manic-depressive psychoses and schizophrenia. Of all the types of psychoses studied, the manic-depressive have shown the greatest frequency of hereditary taint, and this predominately with psychoses.

In the field of neurology, many hereditary diseases are found, such as different hereditary types of muscular dystrophy, Fredreich's ataxia, Huntington's chorea, which is typically dominant; Wilson's disease, in which the brain and liver are involved and which defect is of recessive type; and idiopathic epilepsy, which stands on a definite hereditary recessive basis. Mohr[2] refers to one study of Quincke's angioneurotic edema, in which it appeared as a clear-cut dominant inheritance through five generations, resulting fatally in fifteen of twenty-eight affected family members.

Diabetes mellitus seems to be inherited as a recessive defect, while diabetes insipidus is a clear-cut dominant defect when inherited, and then is due presumably to hereditary dysfunction of the pituitary gland.

The hereditary mechanism of tumor susceptibility has not been demonstrated with any degree of certainty. The somatic mutation theory has been advanced but has not been generally accepted.

Lethal genes may occur through mutation and this may be a sudden, spontaneous alteration in the character of a gene, and this altered character being transmitted thereafter. Ichthyosis congenita in the human is explained on this same basis. This fact resulted in the following unusual occurrence reported by Dr. Mohr.[2] A normal woman gave birth to five normal children by her husband. After his death she had three illegitimate children, all stillborn, having this condition of ichthyosis. Investigation showed that the father of these, though she did not know it, was her own half brother by the same father.

The results of x-ray treatment of eggs and larvæ show some interesting and striking effects, as mutation is increased tremendously, and these changes frequently are like those of spontaneous origin.

Some of the most interesting studies on inheritance have been in the comparisons between various pathological conditions occurring in identical as compared with fraternal twins. These studies made in regard to criminalism suggest that weakness of character may be due to an inherited defect. Dr. D. E. McBroom and Dr. R. W. Brown a few years ago reported at a meeting of the State Neurological Society many interesting observations in connection with a pair of identical twins suffering from epilepsy. Another interesting example of recent observations made in the study of identical and fraternal twins is that susceptibility or resistance to certain diseases may be a transmitted hereditary quality. Thus Dr. Mohr[2] reports in a series of thirty-seven pairs of identical twins that both twins had developed tuberculosis in twenty-six pairs, and only one of the twins in eleven pairs, while in sixty-nine pairs of fraternal twins, tuberculosis was present in seventeen pairs and not present in fifty-two pairs. Among nine pairs where the twins were subject to the same amount of exposure and only one twin became affected, eight pairs were fraternal and one pair identical twins. Conversely, among seven pairs in which both members were affected without known exposure, five pair were identical and two pair fraternal twins. In some of these cases the clinical type was surprisingly similar, such as one in which two identical twin brothers within a four-year period each developed a tuberculous involvement of the bone of the heel. It appears, therefore, that some of the unexpected occurrences in tuberculosis may be due to an inherited resistance or lack of it to the tubercle bacillus.

It is evident that much remains to be learned in regard to the transmission of hereditary traits in man, be they defects or superior qualities. It is apparent, also, that in all of our state institutions a great number of inmates are there, primarily, because of defective germ plasm.

For humanitarian reasons and to reduce the social and economic burden resulting from the presence of various serious defects in man, it should be the desire of society to render prevention in this field as effective as is reasonably possible, although the problem is very complex, and presents vastly greater difficulties than it does in most other fields of medicine.

MUMPS MENINGO-ENCEPHALITIS*

T. L. BIRNBERG, M.D.

Saint Paul, Minnesota

IN recent years, increasing attention has been focused on the meningeal and meningo-encephalitis symptoms occurring in various infectious diseases. Four years ago I reported a series of nine cases of mumps meningo-encephalitis seen during the prior eighteen months.[2] At that time we felt that this complication was of probable cyclic occurrence, appearing only during intermittent intervals in the life cycle of the mumps virus; further, prior reports suggested that this neurotropic tendency of the mumps virus occurred about every tenth year.

Since then, namely, in the past four years, we have observed twenty-nine additional cases of mumps meningo-encephalitis in private practice. So large an incidence in a period of five and one-half years, with no coincidental unusual mumps epidemic, leads us to consider mumps as a disease in which meningeal symptoms appear relatively often, and in the preadolescent age group it has been the most frequent complication we have observed.

The various neurological complications of mumps as noted in the literature include meningitis, meningo-encephalitis, encephalitis, myelitis, and neuritis. As previously mentioned, prior literature has suggested that these complications occur in only some of the epidemics of parotitis, whereas other epidemics are entirely benign in respect to any neurological manifestations. The earliest recorded description of mumps meningitis was that of Hamilton[9] in 1758. During the 19th century descriptions of this complication were recorded by a number of French,[4,5,14,21] German,[6,17] and Norwegian[10,11] authors. In 1902,

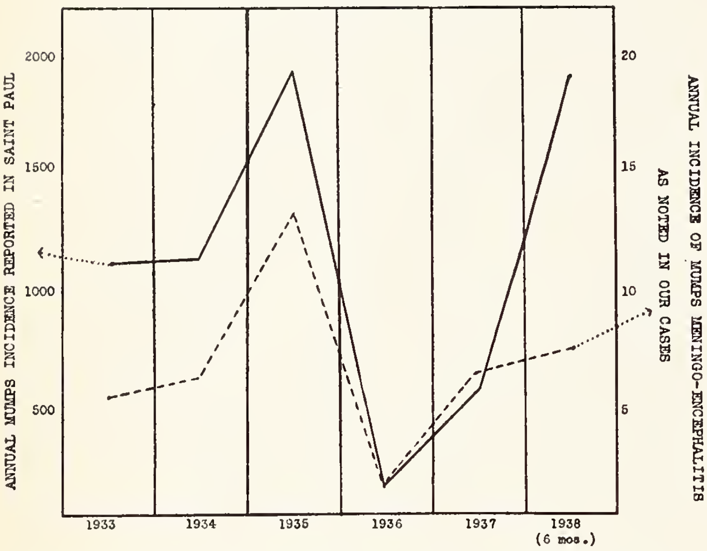
---

*Presented before the Southern Minnesota Medical Association, Rochester, Minn., September 29, 1938.

Monod,[15] reported the first spinal fluid examination made in mumps meningitis.

In 1913, Acker[1] reported two cases of mumps meningitis and collected reports of twenty-seven cases occurring in children, in the literature prior to that time. Subsequent reports are all of relatively small groups of cases; the largest is a group of twenty cases in adults, reported by Silwer[19] in 1936. However, since the disease is rarely fatal and is often very benign symptomatically, many cases have no doubt failed recognition.

CHART I. COMPARISON OF ANNUAL NUMBER OF CASES OF MUMPS MENINGO-ENCEPHALITIS NOTED IN THIS SERIES TO ANNUAL MUMPS INCIDENCE REPORTED IN SAINT PAUL



In an effort to evaluate the comparative incidence of central nervous system symptoms in mumps, we find the literature at great variance and rather misleading. Since mumps cases are commonly never reported, and since in general mumps meningitis is not a reportable disease as such, mass statistics cannot be determined. In individual reports, the author's awareness of the occurrence of such complications is of much significance. Haden[8] found nine cases in 840 mumps patients; Wesselhoeft,[26] two cases in 824 hospitalized mumps patients and Roux[18] three cases in 274 cases of mumps. Larkin,[12] in 1918, found two patients with meningeal symptoms in 2,400 cases of mumps in a training camp. These are all reports of adult groups, and Larkin's figures perhaps give the most accurate index of neurological complications in young adults, but is of too small a group to be significant. Undoubtedly, the most valuable statistics might be compiled from incidence records in orphanages over a long period of years, but no such reports appear in the literature.

The quarantine data in Saint Paul suggests some interesting points as regards the yearly incidence of mumps and mumps meningitis. The City Health Department estimates that about 60 per cent of the cases of epidemic parotitis are reported, largely through school absence checkups. Mumps meningitis is not reportable as such and thus no city-wide statistics of this complication could be obtained. Chart I shows the annual number of reported cases of mumps. The number of cases of mumps meningo-encephalitis seen by us during this same period is also charted for comparison. While our observations include but a small part of the total mumps incidence, the fairly regular parallelism of the two lines suggests that in recent years at least, meningo-encephalitis is a rather constant complication of mumps, rather than of cyclic occurrence as previously observed.

The cases we are discussing are best described as meningo-encephalitis. Although meningeal or encephalitic symptoms may variably predominate, clinically it would appear neither advantageous nor always possible to accurately differentiate the essential localization.

The specific cause of mumps meningo-encephalitis would seem to be either the mumps virus per se or a toxin liberated by the virus. The most decisive work was done by Wollstein.[25] In her experiments she used pooled, filtered mouth washings of mumps patients. The filtrate was injected into cats subcutaneously, into the parotids, and intrathecally, the latter method producing symptoms of meningitis. With the spinal fluid from cats so affected, she was able to produce the disease in other cats. Control tests with filtered saliva from normal humans gave negative results. Gordon[7] in 1913 produced encephalitis in monkeys by intraspinal injections of mumps saliva filtrates. From the case of mumps myelitis reported by McKraig and Woltman,[13] cultures taken from Steno's duct were injected into rabbits with resultant paralysis in eight hours in one case. All these experiments indicate that the virus itself is the causative agent of the meningitis; further, the clinical observance of neurological symptoms before the glandular localization in some cases would tend to negate the virus toxin theory. Whether the virus spreads from the parotid to the meninges directly through the naso-pharynx or through the blood stream is as yet undetermined. One other etiologic approach has recently received consideration. The increase of the various encephalitides in the past two decades is too great to be explained as due to more accurate diagnosis. It would seem possible and plausible that the encephalitis may result either from some symbiotic reaction between the mumps virus and a latent encephalitis virus commonly present in the naso-pharynx, or from activation of such a latent virus during a period of local or generally lowered resistance. True, these are theoretical suggestions, but are mentioned since they may aid in ultimately understanding the entire encephalitis problem.

Since mumps meningo-encephalitis is rarely fatal, pathological reports are few. From the reports of Larkin[12] and Gordon,[7] it appears that there is a congestion of the pia with patchy lymphocytic infiltration along the cerebral blood vessels.

The symptomatology of mumps meningitis is not characteristically distinctive, yet our cases showed a fair degree of similarity. Males are attacked more than females, in our series a ratio of 78 to 22 per cent. While this report includes only children, no age group susceptible to mumps seems immune (Table I).

TABLE I. SUMMARY OF CASES

Total number of cases observed in 5½ years: 38
Sex: Male—29 cases (78%)
Female—9 cases (22%)
Age: Varied from 4 to 14 years (average 8 years)
Onset in relation to onset of parotitis:
Generally 1 to 10 days after onset of parotitis
Definite parotitis never present in 2 cases
Duration: 3 to 11 days (average 6 days)
Sequelæ: One patient had recurrent headaches for 3 months. Subsequently entirely well.
One patient had residual central deafness of left ear.

The clinical symptoms of mumps meningo-encephalitis may appear at quite varying intervals after the onset of the parotitis. The great majority of cases occur in from one to ten days after the appearance of the parotid swelling. Occasionally the meningitis and parotitis develop simultaneously, as occurred in one of our cases. Rarely the neurological symptoms may precede the parotitis by several days, as occurred in cases reported by Casparis,[3] Walker,[22] and Weissenbach.[24] Finally there are some cases in which the meningo-encephalitis would appear to be of undoubted mumps origin by virtue of epidemiological contact, but in which a parotitis never occurs or is so slight as to pass unnoticed. We have noted two such cases (Cases M. H. and D. H.). Similar cases have been reported by Morquio[16] and Wallgren.[23]

TABLE II. SUMMARY OF SYMPTOMS

Noted in 38 Patients

Presenting Symptoms:
Headache only—5 cases (13%)
Headache and fever—14 cases (37%)
Vomiting and fever—5 cases (13%)
Headache and vomiting—11 cases (28%)
Hiccough—2 cases (6%)
Fever only—1 case (3%)
Résumé of symptoms noted during course of disease:
Headache—33 cases (89%)
Vomiting—35 cases (94%)
Fever—All cases (100°-105°)
Lethargy—11 cases (30%)
Irritability—15 cases (41%)
Hiccough—4 cases (11%)
Dizziness—2 cases (6%)

The symptomatology, as noted in the thirty-eight cases we are reporting, shows a fair degree of uniformity (Table II). The presenting symptom is almost invariably headache, often quite intense. Vomiting occurred in practically all cases, but was usually not incessant and persisted for only one or two days. All patients had varying degrees of fever, in some only to 100 mouth; in others up to 105 rectal. Hiccough, lethargy, or irritability were inconstant and usually not pronounced symptoms. Rarely dilated pupils may be an index of cerebral involvement. Convulsions and focal paralysis have been recorded, but have not been observed in our cases.

The neurological examination almost always reveals neck rigidity and a positive Kernig. Variations in reflexes, Tache, Babinski, and pupil changes are not common and have no pathognomonic value (Table III).

TABLE III. NEUROLOGICAL FINDINGS

38 Reported Cases

Neck rigidity: 36 cases (95%)
Positive Kernig: 34 cases (89%)
Reflexes:
K. K. hyperactive—4 cases (11%)
K. K. diminished—6 cases (16%)
Pupils sluggish—2 cases (5%)
Positive Babinski—2 cases (5%)
Tache present—7 cases (19%)

Lumbar puncture was performed one or more times in thirty-three of our thirty-eight cases (Table IV). In all cases the fluid was clear. The pressure was generally slightly increased.

Three cases in which the fluid pressure was measured showed pressures of 10, 12, and 16 mm. mercury. The Nonne test was usually negative; occasionally a faint positive was noted in the phase II Nonne. The cell count varied from 6 to 980, with the usual count varying from 100 to 300. The cells were predominately lymphocytes; the highest polymorphonuclear percentage we noted was 18 per cent. Pedicle formation was never observed. Stained smears made in all fluids showed an absence of organisms. The essential spinal fluid finding, therefore, is a moderate lymphocytic pleocytosis.

TABLE IV. SPINAL PUNCTURE

Performed in 33 Patients

Pressure: Increased in 30 cases (93%)
Cell count: Varied from 6 to 980 (average 100-300)
Differential:
  Lymphocytes: 82 to 100%
  Polymorphonuclears: 0 to 18%
Nonne: Negative in all cases
Pedicle formation: Negative in all cases
Organisms: None found on stained smears in all cases

Of interest is the observation that spinal fluid pleocytosis occurs far more frequently than does active meningeal symptoms in epidemic parotitis. Teissier and Schaeffer[20] examined the spinal fluid in forty-five patients with mumps, nine of whom exhibited clinical symptoms of meningitis. In twenty patients without any neurological symptoms, a spinal fluid pleocytosis was noted. Similar findings are reported by Silwer,[13] with spinal fluid cell counts to 260 in neurologically asymptomatic mumps patients. Various others have reported in small series in which they found 20 to 50 per cent of mumps patients to have increased spinal fluid cell count. This would suggest that asymptomatic meningeal involvement is rather common in epidemic parotitis.

Mumps meningo-encephalitis persists for three to eleven days, with an average duration of about six days. We have found that the temperature returns to normal and the subjective symptoms clear up generally two or three days before the neurological findings are normal. Recovery has been rapidly complete in most of our cases. In one case, recurrent headaches occurred for three months after the acute illness, and then subsided entirely. Another child developed a central deafness of the left ear, which was not complete and later improved. In the literature, various other complications, as optic neuritis, focal paralysis, aphasia, and hemiplegia have been described, but the ultimate prognosis in these cases is usually good.

The differential diagnosis of mumps meningo-encephalitis is usually not troublesome. Essentially an awareness of the occurrence of this complication in epidemic parotitis readily leads to a correct diagnostic interpretation. The presence of mild neurological symptoms in conjunction with a high spinal fluid cell count and a negative Nonne is a valuable diagnostic criterion.

Tuberculous meningitis usually develops slowly; there is a cerebral cry, and the clinical symptoms when fully developed are much more severe. Early there is a higher polymorphonuclear count in the spinal fluid than in mumps meningitis. The pedicle formation in the spinal fluid, the Levinson test, and presence of tubercle bacilli are diagnostic.

Poliomyelitis shows many similarities, but is a disease of the late summer, whereas mumps is most prevalent in the winter and spring. In poliomyelitis, early paralysis and absent reflexes often develop. In the initial stages, the spinal fluid often shows a much higher percentage of polymorphic cells than does mumps meningitis.

Epidemic encephalitis, as well as the various specific encephalitides, are best differentiated by the absence of parotitis or of any definite mumps exposure.

The treatment of mumps meningo-encephalitis is chiefly symptomatic. Spinal puncture should be performed as a diagnostic procedure; it is often of value in reducing fluid pressure, particularly in those cases with persistent headache and vomiting.

Summary

1. A report of thirty-eight cases of mumps meningo-encephalitis seen during the past five and one-half years is made.

2. It is felt that increasing awareness of this complication will result in more frequent recognition and will indicate that meningo-encephalitis is the most common complication of preadolescent mumps.

3. The symptoms generally appear in from one to ten days after the onset of the parotitis and consist of headache, vomiting, and fever, with moderate neck rigidity and positive Kernig.

4. Lumbar puncture shows absent Nonne with a lymphocytic pleocytosis, usually of 100 to 300 cells.

5. The diagnosis rests largely on the recognition that such a complication does occur. To us, the relatively mild symptoms with a rather high cell count is a valuable diagnostic criterion.

# CASE REPORTS

GRANULOCYTOPENIA

WILLIAM D. COVENTRY, M.D.[*]

Duluth, Minnesota

ALTHOUGH agranulocytic angina was described by Schultz in 1922 it is only recently that the various etiological factors concerned have been elucidated. At present it is believed to be a manifestation of drug allergy. Fitz-Hugh,[1] in a recent article on drug sensitivity in relation to certain blood and bone marrow reactions, mentions amidopyrine, dinitrophenol, arsphenamine and neoarsphenamine, gold salts, neostibosan, acetphenetidin, novaldin, causalin, quinine, cinchophen, bismuth, nervinol, plasmochin, and sulfanilamide as proved or suspected causes of agranulocytic angina. Other terms, such as agranulocytosis, pernicious leukopenia and granulocytopenia have been used to describe this condition. The essential hematological reactions are the same in all but as they vary in degree different names are applied. Granulocytopenia is a constant finding and this term has been generally accepted. Under this title I wish to report a case in which the offending drug was probably cinchophen. As only one case of this type has previously been reported it was thought that this presentation might be of interest.

T. R., white, male, a storekeeper, aged sixty-three, entered St. Luke's Hospital on September 20, 1938. He left eleven days later, on October 1, 1938.

His illness consisted essentially of a gastro-intestinal syndrome followed by an attack of polyarthritis. On August 5, six weeks before entrance to the hospital, he developed a pain in the right shoulder with abdominal cramps, and loose stools containing mucus and blood. Such episodes had been experienced before but never had there been blood in the stools. He consulted his local physician, who x-rayed the gastro-intestinal tract completely, with negative results. His symptoms persisted and he consulted another physician, who passed a proctoscope with negative findings. The stool did not appear abnormal but gave a four plus benzidine reaction. It was felt that he had an acute gastro-enteritis, so a bland diet, belladonna and alkaline powders were prescribed. From this treatment he experienced relief. There was a history of alcoholic bouts and this seemed to be the most probable cause of his gastro-intestinal symptoms.

On August 26, three weeks after the onset of intestinal symptoms, and at a time when they were completely relieved, he experienced an attack of polyarthritis involving the right knee, ankle and left wrist. This confined him to bed. After staying in bed for five days he obtained a prescription from a friend who alleged it had relieved his rheumatism. This prescription, which was composed of 7½ grain tablets of cinchophen, was taken one tablet every three hours for the three weeks preceding admission to the hospital. It gave him complete relief, especially when interspersed with anacin, of which he took about forty-eight tablets during this period. He was feeling quite well on this medication till several days prior to admission, when he developed chills, fever, somnolence and delirium.

In his past history it was noted that he had had rheumatic fever at the age of thirty-eight. No history of venereal disease could be elicited. There was also the history of alcoholism previously mentioned. He had always been noted for a stubborn, perverse personality.

On admission to the hospital he was acutely ill, irrational and delirious. His temperature was 101.6°, pulse 98 and respirations 24. The eyes showed arcus senilis and an icteric tint to the scleræ. There was no discharge from the ears. The nasal septum was deviated to the left and some serous secretion was present. The mucus membranes of the mouth were slightly pale, and the tongue was coated. There was edema and redness in the right peritonsillar area with erosion at the upper pole. The tonsil was enlarged. No actual ulceration was present. The neck was negative. No lymphadenopathy was present in any region. There were moderately coarse râles and dullness at both lung bases but no signs of consolidation. An x-ray of the chest was negative except for an

azygos lobe. The heart tones were distant, but regular, and there was no enlargement. The abdomen was slightly distended but no organs were felt. The extremities showed no deformity. The reflexes were equal. Rectal examination showed slight enlargement of the prostate.

Laboratory examination revealed a hemoglobin of 71 per cent, erythrocytes numbered 3,470,000 and there were 2,600 leukocytes per cubic millimeter. A differential count revealed a complete absence of polymorphonuclears, with 61 per cent lymphocytes, 25 per cent metamyelocytes and 14 per cent myelocytes. Severe toxic changes were present. Several days later the platelets were found to be 365,000, reticulocytes 2.2 per cent, coagulation time 5 minutes and bleeding time 2 minutes. The icterus index was 14. Urinalysis showed two plus albumin. Later specimens were normal. Repeated stool examinations were negative. The Kline and Kahn tests were negative. Blood cultures were negative.

A sternal puncture was performed the day after admission. Films from the puncture material showed a paucity of mature granulocytes with an increase in metamyelocytes. Toxic changes were present. Nucleated red blood cells were scarce. There appeared to be a severe toxic depression of all marrow elements.

On September 22, forty-eight hours after admission, treatment with pentnucleotide was begun, 10 c.c. being given intramuscularly every six hours. The next day the white blood cells numbered 5,200 and 10 per cent polymorphonuclears were present. The following day the leukocytes were 7,500 and there were 43 per cent adult neutrophiles. On September 24 a 500 c.c. blood transfusion was given. Following this the white count reached 12,700 and the neutrophiles reached 45 per cent. For the remainder of his hospital stay the leukocytes ranged from 11,750 to 17,300 and the neutrophiles finally reached a peak of 73 per cent. In all, 60 c.c. of pentnucleotide were given. The hematological data are given in Table I.

Coincident with the improvement in the blood there was a sharp fall in temperature and pulse, and clinical improvement followed. At the time of discharge there was still some elevation of temperature and he complained of soreness and limitation of motion in the left wrist. He refused to be hospitalized longer.

Since discharge from the hospital he has been treated with iron, salicylates and local heat. The arthritis in the left wrist has subsided but he still has some aching on the dorsum of his hands and feet. While he was home he took one tablet of cinchophen. Fever and a generalized tingling sensation resulted. He has taken no more anacin. On November 1, one month after leaving the hospital, his hemoglobin was 78 per cent, erythrocytes 4,280,000 and leukocytes 9,400. The blood film showed 61 per cent neutrophilic polymorphonuclears, 4 per cent eosinophilic polymorphonuclears, 28 per cent lymphocytes and 7 per cent monocytes. The sedimentation rate was 25 mm. per hour.

The sequence of events in this case appears to have had its onset with a rheumatic fever which was treated with cinchophen and anacin (acetylsalicylic acid gr. III, acetphenetidin gr. 1½, quinine sulphate gr. ½, caffeine gr. ½) and culminated in granulocytopenia appearing three weeks after the commencement of medication. Numerous drugs are known to be capable of producing this syndrome through acquired sensitivity. Cinchophen, acetphenetidin and quinine are among these and one of these three substances probably operated etiologically in this case. Skin tests with the drug directly or after mixture with serum have not been very successful in detecting the offending drug. The actual ingestion of the substance followed by study of the blood is the best method of detection. I regret that this was not possible, but from the evidence presented by the patient, which was substantiated by his wife, it would seem that cinchophen was the cause of the granulocytopenia in this case. The icterus could also be explained by the action of cinchophen, for it is well known that this drug may produce a toxic hepatitis.

A case of agranulocytosis due to cinchophen has been reported by Shapiro and Lehman.[2] Their patient suffered from polyarthritis and a urethral discharge. He took 7½ grains three times a day for three weeks before symptoms developed. Blood counts on the fourth day of illness revealed a hemoglobin of 68 per cent, erythrocyte count of 3,680,000 and leukocytes numbering 3,000. The blood films showed segmented neutrophiles 1 per cent, non-segmented neutrophiles 2 per cent, eosinophiles 2 per cent, lymphocytes 93 per cent, monocytes 1 per cent, myelocytes 1 per cent. Icterus index was normal. Pentnucleotide (exact amount not mentioned) and transfusions were given and a leukocyte level of 4,000 was reached in seven days. The patient recovered. Sternal puncture on the twelfth day of the illness revealed a hyperplasia of the bone marrow with predominance of the younger granular elements.

The nature of agranulocytic angina and allied blood dyscrasias such as purpura and hemolytic anemia as affected by drugs has recently been discussed by Fitz-Hugh.[1] It is essentially a drug allergy, that is, an acquired sensitivity. No reaction follows the initial dose of the drug, but with repeated administration, sensitivity is increased until very small doses cause profound reactions. This occurs only in individuals who are conditioned for it. The factors responsible for this conditioning are multiple and at present not clearly defined but they probably include genetic influences, endogenous toxic factors, vitamin deficiencies, and endocrine factors associated with menstruation. Fatigue states and traumatic shock also play a part. In the case at hand subclinical hepatitis due to alcoholism or cinchophen may have been a conditioning factor.

The pathology of granulocytopenia is concerned with a maturation arrest. The bone marrow shows an active proliferation of immature granulocytes with absence of mature forms. When the offending drug is removed or when stimulus to normal maturation is provided, marked regeneration is evidenced by immature granulocytes appearing in the peripheral blood. In this case cessation of maturation was not complete, therefore regeneration with the appearance of myelocytes and metamyelocytes in the peripheral blood was present during the acute phase of the disease.

In conclusion, it is suggested that patients who are receiving drugs likely to produce acquired sensitivity be closely observed, especially when conditioning factors may be present.

INTUSSUSCEPTION OF THE BOWEL IN ADULTS

WALTER HALLORAN, M.D.
Jackson, Minnesota

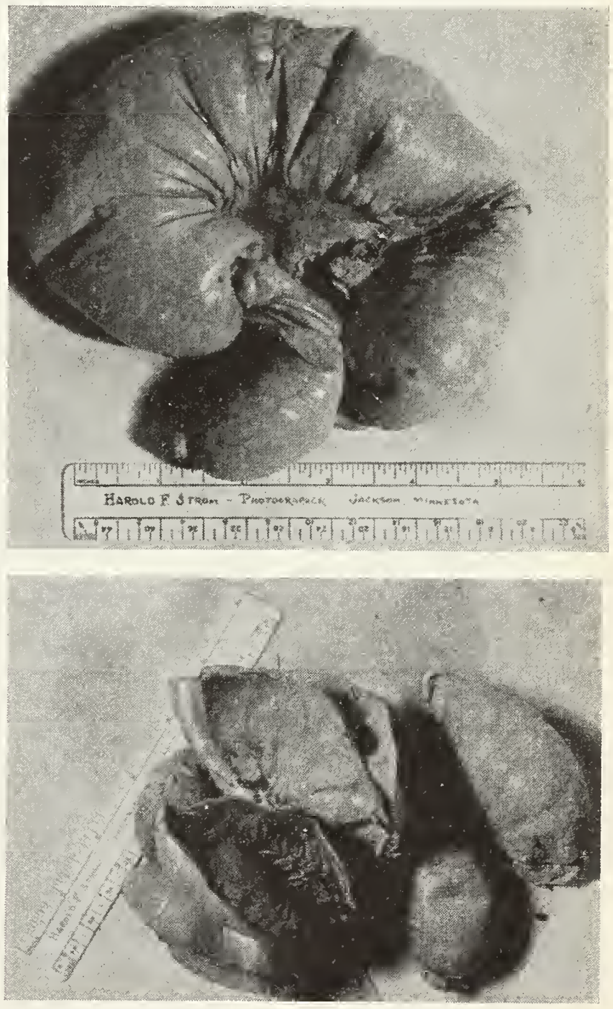
IN CASES of intussusception of the bowel in adults, a pedunculated tumor of the mucous membrane of the intestine has frequently been found to be associated. The following is a report of such a case:

Mrs. A., aged twenty, stated that for the past year her stools has been as a rule unformed and more frequent than formerly. Three weeks before, she had an attack of acute abdominal pain and vomiting which was abrupt in onset and lasted for about three hours. The present attack began about six hours before she was first seen by us, with sudden onset of rather severe abdominal pain, intermittent in character. She was vomiting small amounts frequently and was given a hypodermic injection of morphine gr. ¼ and atropine gr. 1/150 and sent to the hospital.

Physical examination showed a well nourished female, not having much pain at that time. Temperature was 98.4, pulse 72, respirations 18. General examination aside from the abdomen was essentially negative. There was no distention, she having had a liquid stool about three hours before. There was slight resistance and tenderness in the right lower quadrant but no mass could be felt. Pelvic examination showed slight tenderness to the right of the fundus of the uterus. The urine was normal; leukocytes 14,000. A diagnosis of acute appendicitis was made and the patient prepared for operation.

A muscle splitting incision was made on the right. There was dark blood-stained fluid free in the peritoneum. The appendix was kinked and the distal third was a little tense and injected but not acutely inflamed. There was an intussusception in the distal third of the ileum. As the mass was dark, edematous and friable and could not be reduced, it was resected and a lateral anastomosis made. The abdomen was closed with one penrose drain. Convalescence was delayed by an infection which developed in the cul-de-sac which was drained through the vagina. She left the hospital on the twenty-eighth day in good condition.

The resected mass comprised 22 inches of the ileum. A pedunculated tumor of the mucous membrane 2.5 inches in length by 0.5 inch in diameter presented in the lumen of the bowel at a point just distal to the point where the intussusceptum entered the intussuscipiens. This was evidently the cause of the obstruction.



(Above) Segment of ileum removed.
(Below) The bowel has been opened showing a pedunculated tumor of the mucous membrane.

The interesting feature of this case is the fact that the symptoms were not at all alarming. After the first attack of acute pain the patient had little or no pain and the pulse and temperature were normal, while the bowel at the time of operation had already undergone irreparable damage.

HISTORY OF MEDICINE IN RAMSEY COUNTY

BY J. M. ARMSTRONG, M.D.

(Continued from February issue)

1862

The war was now seen to be an affair of more than a few months. The physicians of Saint Paul who received commissions in the army were Dr. Wharton, surgeon to the Second Regiment, Dr. Vervais, assistant surgeon to the Fifth Regiment, Dr. Rieger, surgeon to the Eighth Regiment, and Dr. Rosenk, first lieutenant in the Second Battery Light Artillery. Dr. Hand, late in the year, was made medical inspector of the second corps of the Army of the Potomac, and Dr. Thomas Foster acted as commissary of prison camps and hospitals in Ohio.

As regards Rosenk, an amusing incident occurred showing the need of men for the army and the patriotism of our police court. It seems that one Von Glahan entered a complaint on April 17 against Rosenk for $2.50 for goods purchased. As Rosenk was under marching orders, Von Glahan evidently feared that he would not get his money. On Sunday he went to Rosenk's house to collect the money and Rosenk kicked him out; hence the complaint. After due consideration the court fined Von Glahan five dollars and costs for presenting his bill on the Sabbath day. The bill was probably for liquor, for a short time later Von Glahan was arrested and fined ten dollars and costs for selling liquor without a license; the fine was paid in city scrip, then worth ten cents on the dollar. Apparently bootlegging had its hazards then as now.

The governor appointed Dr. Willey to be chairman of the medical board for Minnesota to examine candidates for the positions as surgeons and assistant surgeons in the army. The Saint Paul Academy of Medicine and Surgery this year, despite the fact that most of its members were in the army, was an active organization, and the officers for 1861 apparently were elected at the annual meeting on the first Tuesday in May. They were: A. G. Brisbine, president; Samuel Willey, vice president; John Steele, treasurer; Alfred Wharton, secretary; and D. W. Hand, librarian. In January the Academy procured the services of Dr. D. B. Reid to give again a course of public lectures on chemistry at the Academy rooms in French's block on Third Street. French's block, a three story stone building, stood between Market and Washington Streets on the north side of the street. At this time George Benz's liquor establishment occupied the ground floor. The Academy had rooms on the second floor and Union Hall was on the third floor.

Dr. David Boswell Reid (1805-1863) graduated in medicine at Edinburgh in 1830 and was made a member of the Royal College of Physicians there the following year. In 1833 he was assistant to Dr. Thomas C. Hope, professor of chemistry at Edinburgh. The catalogue of the surgeon general's library lists thirteen titles by him. His system of ventilation, sanitation, and acoustics was adopted in the construction of the parliament building in London and St.

George's Hall in Liverpool. He was living in London in 1847. The reason for his coming to Saint Paul is unknown; possibly he came for his health. Upon his return to the East he gave lectures at the Smithsonian Institution and served as a member of the United States Sanitary Commission. He died in Washington, D. C., April 5, 1863; his family were resident in Saint Paul at the time of his death.

Dr. Vaiden, mentioned as a resident as early as 1855, and the writer of the book "America Vindicated" (probably the first book by a Saint Paul author and certainly the first by a Saint Paul physician), in January announced as the subject of a lecture to be given by him on January 8, "Human Government, What it is and ever has been—Empire; and what all Government should be * * *." The lecture was given at the court house and was favorably commented upon by the papers. Some time later he was assaulted on the street, but the assault seems to have been due to some disagreement over business deals rather than to any statements made in his lecture.

Among the new physicians who located in Saint Paul in 1862 was Dr. Underwood, of Chicago, who announced himself as an "eminent operator on the eye and ear." As he was a liberal advertiser he was able to secure a number of reading notices in the papers. He established himself at the American House. Wm. H. Duval, M.D., late of Brooklyn, N. Y., opened an office at Eighth and Wacouta Streets. Dr. Simonton, dentist, also came at this time and as he resided in Saint Paul for many years his arrival is worth recording. For a time he had an assistant named Dr. Hopkins from Boston. On September 2 appeared the first advertisement of "Dr. Galen's Dispensary and Venereal Infirmary, Chartered by the Legislature of Kentucky." This institution solicited business at its branch office in Concert Hall block on Third Street, and was conducted by Dr. Thaddeus Williams. It was later called the Galenic Institute. Thaddeus Williams was an elder brother of the late Cornelius Williams of Saint Paul. He sold the Galenic Institute to a Dr. J. W. Nabersberg in 1872 and died in Milwaukee about 1875. Dr. Nabersberg died in Saint Paul about 1920.

Captain Samuel Painter, of Saint Paul, who advertised in 1861 to cure cancer in less than twenty days "no cure no pay," continued his advertising. Dr. Brisbine was elected city physician at $400 per year, with the understanding that he would furnish his own medicines. Dr. Steele was elected alderman for the first ward for three years. Dr. Potts, whose term expired in March, was chosen to fill the vacancy on the School Board occasioned by the resignation of B. D. Beveridge in the second ward. The pension office was instituted in Saint Paul for the first time in 1862, and Dr. Samuel Willey and Dr. C. E. Cross, of Rochester were appointed examiners. It may be noted that Dr. Tavernier's house on Fourth Street caught fire and was damaged to the extent of $500 on April 3; that Dr. Berthier left in August for a three months' visit to France, and that Dr. Alberti was still in town. Dr. Wren, formerly of Saint Paul and later post surgeon at Fort Ripley, located in Saint Cloud, associating himself with one Dr. Palmer. Dr. Massey, who was at this time editing and publishing the *Press,* obtained by competitive bid the contract for the city printing. As his paper was anti-war in policy, a considerable political furor was aroused and the city council was obliged to rescind its action and give the contract to the *Pioneer*. Dr. Wm. Caine, prompted no doubt by a vicarious desire to suppress the Sioux Indian uprising, offered $25 for five Sioux scalps. Crops were bad this year and many people had difficulty making a living. It was then discovered that ginseng was plentiful in our woods and many made a living digging it. The price received then was only fourteen cents a pound; nevertheless on November 8 the barge *Minnesota* arrived from Saint Peter with twelve tons of the product on board which was sent to Baltimore for shipment to China. In all 241,245 pounds of it were shipped from Saint Paul during the year. The *St. Anthony News* stated that the sum of $80,000 was paid out for gingseng brought into that city during the previous year (1861). The removal to Nevada of Dr. C. L. Anderson, who settled in Saint Anthony in 1852, was recorded as having taken place on May 13, and his value to the state and government as a botanist and geologist was lauded. Dr. Rosenk apparently did not find army life congenial; for that or for some other reason he resigned his commission, and late in 1862 he returned to Saint Paul and advertised himself as a physician and surgeon, accoucheur, and dentist. In the *American Medical Times* for March 15 and 22, 1862, is printed an article on "The Climate of the State of Minnesota, and its adaptation to persons suffering from Phthisis Pulmonalis" by George Lewis, M.D., of Saint Paul, Minnesota. This is an extensive statistical study of the climatic conditions of Minnesota and is typical of the period in which it was written. The author was evidently from New York city, and the lack of any record of his practicing medicine in Saint Paul leads to the suspicion that his sojourn there was for the benefit of his health. The same journal for April 5, 1862, contains a card stating that William H. Davol, M.D., late physician to the Long Island College Hospital, Brooklyn, had removed to Saint Paul. This man's name in the Saint Paul papers is spelled Duval.

1863

This was the most discouraging year of the war and political discontent both in local and national affairs is markedly indicated in Minnesota papers. All the members of the Saint Paul Academy of Medicine and Surgery were in the public service except Drs. Willey, Steele, and Brisbine. Willey was tuberculous, Brisbine too large and heavy to serve, and Stewart was on parole though attached to a skeleton regiment. The pension service office was now so busy examining claimants that regular office hours were established. Drs. LeBoutellier and Dewey were surgeons of the Ninth Regiment. Shortly before the first of the year a Dr. William E. Barnes took up his residence on Seventh and Jackson Streets, though he hardly could have become settled until the first of the year. He stated that he might be consulted in either the English or the German language and would give particular attention to diseases of the lungs and throat. As his advertisement disappeared from the papers about four months later, he presumably remained only a short time. Dr. De Montreville, a dentist, took offices in French's block, where he remained many years. Dr. J. H. Stewart now made his first political venture, running for mayor, but was defeated. Dr. Brisbine, however, was elected school inspector for the fourth ward. The state legislature this year made an arrangement with the state of Iowa relative to the care of insane Minnesota residents in the Iowa Hospital for the Insane. As an instance of lunacy in Saint Paul, the *Pioneer* for May 25 cited the case of one Dr. Seimers who paid "half a dollar in silver as a fee for admission of a friend as a member of the Democratic Club." Apparently in the eyes of the *Pioneer* he was insane on two counts. As to Dr. Seimers, inquiry has elicited only the further information that he still owed Dr. Brewer Mattocks the sum of $2.50 *in gold;* at least Dr. Mattocks said so. Where anyone obtained gold at this time is a mystery, as the only money in circulation was "shin plasters." Perhaps if the editor of the *Pioneer* heard of Mattocks' having loaned Seimers that amount of gold, a second case of insanity might have been noted. The arrangement made by the Saint Paul Academy of Medicine and Surgery with the city council was still in force and we find that the members took turns acting as city physician. Willey served in April, Stewart in May, Potts in June, Steele in July, Stewart in August, Willey in September, Brisbine in October, and Steele in November. During this year the salary of the city physician was reduced to $300 per annum, but the Academy secured the position of county physician also at a salary of $100 per year. In 1862 Drs. Caine and Williams held the latter position.

In April the papers announced the death of Dr. LeBoutellier at Saint Peter, where he was then stationed. Dr. Vervais, who was assistant surgeon to the Eighth Regiment, resigned and arrived home in May and Dr. Armington of the Second Regiment also resigned. Although Armington was not a resident of Ramsey County, he lived across the river in Dakota County, possibly within the present limits of the West Side or West Saint Paul. It was later than this that the city of Saint Paul extended its borders on to the west bank of the river. Dr. Hand was captured by the enemy in May but was released and returned to his command. An arrangement was made between the two armies that medical officers should not be held prisoners.

Several new physicians came to Saint Paul this year. Dr. John H. Murphy moved over from St. Anthony in August, having resigned from the army on account of sunstroke. The rest of the newcomers were transient visitors of the advertising ilk. Dr. Phillip H. Hershey, oculist, aurist, and chemico-electropathic physician, established himself at the American House in June and remained about a month. Dr. Kennedy of Cincinnatti remained at the Merchants Hotel for a short time. He advertised to remove corns, bunions, warts, chilblains, and ingrown nails in from five to fifteen minutes. Dr. Benjamin Durkee established himself for a short time in September at the Minnesota House. He advertised "Dr. Benjamin Durkee's or The Poor Man's Eye Water," a panacea for all ocular affections. In May Dr. Rosenstraus, practical optician and spectacle maker, was at the American House for a week; and in September, Prof. M. Bernhardt, consulting and practical optician, was at the International Hotel. This man apparently obtained the confidence of the medical profession for he published recommendations from Drs. Willey, Stewart, Potts, and Steele. Bernhardt stayed in Saint Paul a month or two, then went to Saint Anthony, and Saint Cloud, and possibly to other towns. It is noted in the papers that measles broke out in the Indian camp at Fort Snelling in January, and that several deaths had occurred.

In May a discussion arose at the meeting of the city council relative to the care of city and county patients. It has been recorded previously that St. Josephs Hospital, or the building that had been built for that purpose on the present site of the hospital, had been closed, and that the old chapel of Saint Paul was used for the hospital. The original hospital building was used to house the Sisters. The surmise was made also that most of the city patients had been sent to the poor farm for treatment. This last is confirmed by a resolution passed by the council: "In general, patients should be sent to the County Poor Farm, but the Sisters' bill should be paid." This probably means that some city patients had been cared for at St. Josephs Hospital. This procedure was probably an economic measure. In August the council failed to pass a motion allowing ten dollars to Mary Cool for the use of her house for a negro having smallpox. In October the Hospital was moved back to the original St. Joseph's building on Exchange Street; since which time it has not been closed. An announcement in 1862 stated that private rooms might be had for $5.00 per week and ward beds at three dollars not including medicine and medical attendance. Patients were allowed to select their own physicians. In December the Saint Joseph's Academy building on Nelson Avenue was completed, having been started in 1862. The Sisters moved in from the two log buildings in Bench Street which were then abandoned.

On August 9 an article "Why Should the Climate of Minnesota Contribute to the Cure of Consumption" by Rev. S. Y. McMasters, M.D., was printed in the *Pioneer.* This seems to have been the first medical article by a resident to appear in print in our daily papers. Dr. McMasters came to Saint Paul as rector of Christ's Episcopal Church in 1862. He had studied medicine and also had taken clerical orders. In August an examining board appointed by the adjutant general of the state for the examination of medical officers for Minnesota regiments appointed George McD. Lambert second assistant surgeon to the Fourth Regiment, and E. Brewer Mattocks second assistant surgeon to the Seventh Regiment. Both men were residents of Saint Paul. The latter was a son of the Rev. John Mattocks, rector of the First Presbyterian Church. Lambert had been a hospital steward for some time and Mattocks was also a hospital steward in a volunteer regiment. While stationed at Saint Louis he had attended lectures at a medical school there and received a diploma. He was also a graduate of the Pennsylvania School of Pharmacy. Lambert practiced medicine in Stillwater after the war was over, and Mattocks settled in Saint Paul. Mattocks was the last survivor among the founders of the Ramsey County Medical Society, of the State Medical Association, and of the Minnesota medical officers of the Civil War. He resided at the Soldiers Home at the time of his death in 1934. The board which conducted this examination consisted of Drs. Stewart, F. R. Smith, and Brisbine. Dr. John Henry Seimers apparently was not very successful as a practitioner of medicine for he accepted the position of assistant jailer at the county jail, under Sheriff D. A. Robertson. Dr. Berthier left Saint Paul this year. He advertised for sale his residence, on the corner of Seventh and Wacouta Streets, and a small stock of medicines, glass jars, scales, et cetera. The newspapers stated he was going to return to France. Dr. Wharton, who remembered him very well, stated that he was a man of some ability though he was regarded as an irregular practitioner by the profession in Saint Paul.

Two events of quasi-medical interest were recorded this year. The first railway accident occurred when Capt. Abraham Bennett was killed, his buggy being struck by a train at the Lake Como crossing on July 3. In May a local undertaker brought the first hearse to Saint Paul. The *Pioneer* stated, "It is decorated with ostrich plumes and is fit for a Sybarite."

In the first part of this narrative mention was made that in the early days a cemetery was located on Jackson Street about where the city market now is. Apparently this fact had already been forgotten, for on October 2, Coroner Strother was called to view a body enclosed in a coffin that was exhumed while a lot was being graded at Jackson and Pearl Streets. The body was identified as that of D. B. Freeman by A. L. Larpenteur, who was Freeman's partner at the time of his death in 1849. This cemetery was on land owned by B. F. Hoyt, who allowed burials there. In addition to the names of physicians already given, the city directory for 1863 gives the name of one D. O. Regan as a botanic physician.

1864

Dr. Thaddeus Williams, of the Galenic Institute, hit upon an ingenious scheme to obtain the names of tuberculous patients in this vicinity. He published a reading notice in the papers of February 2 under "A Card to the Public," stating that he was preparing (by request) a paper for the *American Journal of the Medical Sciences* on "The Climatic Influence of Minnesota on Phthisis Pulmonalis," and asking the city physicians and those throughout the state to communicate with him. He listed fourteen questions he desired to be answered and requested the names and addresses of patients, promising, however, not to use names in the article in cases where publicity was not desired. Whether this brought in any number of names of persons to whom he might send his advertising literature is not recorded, but a perusal of the above named journal has disclosed no article on tuberculosis by him. A few days after his "Card to the Public" appeared, another notice appeared which throws some light on his history. In the letter he stated that he had been engaged in practice in Louisville, Kentucky, before coming to Saint Paul, and gave as references the names of several physicians in Louisville and Cincinnati, who probably enjoyed a doubtful reputation.

To physicians who served in our last war, it seems strange that a commissioned officer could resign from the army so easily during the Civil War. Dr. Reiger resigned and returned to Saint Paul in April, and Dr. Wharton resigned in August and returned in September. In the meantime other Saint Paul men entered the army. Dr. Robert L. Morris was commissioned assistant surgeon of the Eleventh Regiment, and Dr. Percival Barton, of West Saint Paul, assistant surgeon of the Seventh Regiment. Regarding Morris, no information is available. Barton, however, graduated from the University of Pennsylvania in 1849. While not a resident of Saint Paul, he lived near enough to be noted here. He spent the last years of his life on his farm at Inver Grove.

Although Dr. Rudolph Alberti lived in Saint Paul during the previous decade he had not up till this time advertised in the papers. In 1865 he announced that he was a graduate of the University of Berlin and that he could be consulted in the English, French and German languages. Three new physicians, other than those of the quack variety, became residents of Saint Paul this year. Martin Fossion, a French physician, arrived in May; Dr. H. Van Buren, late of Chicago, in July; and Dr. W. R. Simpson, of the Universities of Edinburgh and Dublin, in October. None of them remained more than a few months. As usual, the itinerant "doctors" were in evidence. Among them were Dr. Benjamin Phelps, oculist and ophthalmologist; Dr. Trallwill, who lectured on hygienic medication; and a Dr. Crees, "an old experienced medical electrician" who opened a hygienic boarding house on Seventh Street below Broadway. He came from Saint Anthony, where he had been connected with an institution of a similar character.

An incident worth recording, perhaps, regarding Dr. Murphy may be given here. While hunting near Fort Wadsworth he was thrown from his horse and gored by a buffalo bull which confined him to his bed for a fortnight. Smallpox was rather more prevalent this year than usual, and the city council felt justified in building a temporary hospital for contagious and infectious diseases, in July, on the county farm. A party agreed to finish it in a week at a cost of $130, and in October an appropriation of $49 for the care of these patients was approved.

The ginseng gatherers were busy again this year and during the week preceding October 16, 50,000 pounds were shipped out of Saint Paul. Most of this came from the vicinity of Taylor's Falls, and the competition among buyers became keen, the price rising from 25 cents to as high as 40 cents a pound for the green root. At the present time the wild root is very scarce and it would be a difficult task to gather a single pound in a day in the same locality.

As most physicians are sportsmen, it may be noted that three hunters killed sixty bears in the four weeks ending October 16 in the vicinity of Taylor's Falls. Deer also were very plentiful. Forest fires were prevalent in the north during the early autumn, and no doubt drove the game southward. The writer must refrain from repeating any of the fish stories reported. As regards politics, Dr. Stewart was elected mayor, and Dr. Brisbine school inspector for the fourth ward. The Saint Paul Academy of Medicine and Surgery still held the positions of city and county physicians. Brisbine took care of the offices in January, and Stewart in March. There is some question as to who acted for the other months. Dr. Mann was elected president of the State Agricultural Society. The directory for 1864 lists as physicians, John P. Kenna and Frank Dade. As their names appear in no other place they apparently remained in Saint Paul but a short time or else were obscure men. In June of this year the Protestant Orphan Asylum was organized, the officers of which were Mrs. Walter Webb, president; Mrs. S. Y. McMasters, vice president; Mrs. John Mattocks, treasurer; and Miss Postlewait, secretary.

An interesting episode regarding a physician occurred early in the year. It was the conviction of one Dr. J. W. Dibbs, of Saint Anthony, who was charged with attempting to secure fraudulent exemption of two drafted men from military service. Dibbs injected air, with a pump, under the skin of the chest of the men in order to simulate emphysema. Dr. Stewart detected the fraud. Dibbs confessed and stated he had received $25 from each of the men. Dibbs had been surgeon to Captain Fisk's expedition of 1863-1864.

Other disasters overtook two of our physicians during the year. A son of Dr. Thaddeus Williams fell into a cistern adjacent to his home and was drowned. Dr. Dewey's house was partially destroyed by fire and his valuable library totally destroyed. Of our physicians who were in the army, Dr. Rieger returned in March and Dr. Morton in December.

The year also marks the date of the first medical books issued with a Minnesota imprint. They were issued by the Galenic Institute; one was "A Private Medical Treatise," 350 pages, 110 illustrations; the other was, "The Youths Manual." Both were priced at one dollar and were of the type still issued by advertising medical institutes.

Drs. Murphy and Wharton now became associated and Drs. Caine and C. D. Williams dissolved partnership. Brewer Mattocks became understudy to Dr. Stewart. Stewart evidently needed an assistant as he was now mayor, surgeon of the board of enrollment, director of the Superior Railroad and the Second National Bank, and vice president of the Home Insurance Company, and was about to be appointed postmaster. A Dr. James Hunter now appeared in Saint Paul and advertised extensively in the papers. Only one reputable physician seems to have entered practice here this year. He was Dr. J. M. McMasters, a son of the Rev. Dr. S. Y. McMasters. He associated himself with Dr. Brisbine. He had been a hospital steward in the regular army, and although he returned to Saint Paul at this time, he did not receive his diploma till the following year. Later he moved to Sioux Center, where he resided many years. He died in Indiana at the home of his daughter in the second decade of this century.

(To be continued in April issue)

President's Letter

ON THE question of our relations and adjustments to the public in the practice of medicine, the office is receiving considerable comment and suggestion, particularly on the various phases that are being discussed in all of the popular magazines. The number of letters on the subject is so large that we cannot begin to mention the names of the writers. These letters and suggestions are all given careful consideration and they provide an important index of the opinion of the practicing profession on the questions at issue. Such interest should have the effect of uniting organized medicine in its study of the questions involved. The best studies can probably be made in small groups, formal or informal, where viewpoints are freely expressed.

Group medical plans are being studied or are in force in the following places: California, Michigan, Seattle, Washington; Missouri, Cleveland, Ohio; New York, Wisconsin.

The public is asking us for leadership without realizing apparently, that the questions involved are just as complex and human as problems regarding housing, clothing, personal relationships in the family, and all of the other conditions that enter into human health and happiness. Some people appear to feel that a medical heaven on earth can be brought about through some form of legislation. We find, however, that when we point out to individuals and groups the taxation involved in state medicine, also some disadvantages of government management and the danger to their own freedom of choice of physician, they commence to think of the practical implications.

The problem before us is that of presentation of the viewpoint of organized medicine so that the public will understand that we are anxious for adequate medical care and that we always strive to be progressive; that, if we question certain viewpoints, it is because we doubt their ultimate value or the practicability of carrying them out.

The practicing profession of Minnesota has stood behind and aided in the establishment of our state institutions for the mentally deficient, for tuberculosis, for public health boards and for our University. We have not taken a narrow attitude on these questions and we believe that there are many other problems in which the state is vitally and necessarily interested. These things should progress and gradually develop; but organized medicine also believes that voluntary practice has an important role in the health of the state.

The program of the month for March calls for Degenerative and Circulatory Diseases (including heart, kidney and diabetes). That interest continues is evidenced by the requests to the State Office for packets on the various monthly subjects. Interest is further evidenced by continued suggestions of subjects. Dr. O. H. Wangensteen called attention to the fact that appendicitis is still a major unsolved problem in the practice of medicine. Dr. B. J. Branton writes that nervous and mental conditions have been suggested to him as another important subject due to the general tension evidenced, not only here, but throughout the world. Probably we can work these subjects in; if not, and the program proves of continued interest, such subjects will be given consideration next year and the State Office will be very glad to have continued suggestions and constructive criticisms.

A.M.A. INDICTED

IN AN editorial entitled "Group Hospital Association, Inc." which appeared in the September number of Minnesota Medicine, were related the essential facts pertaining to the proposed Grand Jury investigation of the Medical Society of the District of Columbia, the A.M.A., and some nineteen physicians by the United States Department of Justice. Some additional matters in connection with the investigation are worth mentioning.

On December, 1938, while the matter was pending before the Grand Jury a special assistant to the Assistant Attorney General Arnold, by the name of Douglass Maggs, announced in a public address at Milwaukee, the charges being made by the government, which were given widespread newspaper publicity. All lawyers know that the Grand Jury is the outcome of centuries of struggle on the part of the Anglo-Saxon race for freedom from unjust arrest. A Grand Jury made up of fellow citizens hears evidence in secret and determines whether arrest and trial are warranted. This attempt on the part of a lawyer in the Department of Justice to influence the course of Justice is not in accord with the accepted American idea of fairness. This is not the first time that Arnold has attempted to use propaganda in advance of a Grand Jury indictment.

Another measure has been used in the indictment of the A.M.A. in an effort to force the ideas of Assistant Attorney General Arnold on the medical profession. An offer was made to request the Court for a consent decree providing the A.M.A. would go far beyond the legal requirement in acquiescing to the demands of the government. Such a consent decree by the Court would have the authority of law, and thus the views of Arnold would establish the law instead of legislative bodies and the courts. This is not the first time that this method of obtaining a consent decree has been used by Arnold.

It is to be hoped that our A.M.A. officers will not be intimidated. Arnold has declared that criminal proceedings are much more effective than civil suits. Thus the physicians of the country are being indicted for actions alleged to be criminal.

The A.M.A. has been indicted for activities alleged to be in restraint of trade. It is unfortunate that the practice of medicine is labeled a trade. Although commercialism in medicine is admittedly too often in evidence, medicine is still a profession, the distinguishing feature being that money is not the prime consideration. There is plenty of evidence that science and service of humanity are still of more importance to the medical profession than financial return.

It was perhaps inadvisable for the medical society of the District of Columbia to expel members for other reasons than moral turpitude.

A medical society member has certain legal rights even in a society which has free rein in admittance to membership. It is unfortunate, too, that this test case is to be tried in Washington where members of the jury may well be prejudiced in advance simply because they live in a locality from which emanate ideas favoring changes in medical practice. We cannot, however, blame the medical profession of Washington for being militant in defense of private practice. The Group Hospital Association, Inc., though limited to the Home Owners Corporation employes, may well be expanded to include all government employes in Washington, which would mean government controlled medicine in our capitol.

Incidentally, the term "socialized medicine" is a poor one and should be dropped. Medicine is already socialized. What is opposed by the medical profession is government controlled medicine, with its political appointments, loss of free choice of physician, loss of free initiative in a country in which free initiative is still supposed to exist in other activities.

No one welcomes a suit and particularly a criminal suit. In spite of innocence, anyone will make every effort to avoid the publicity incident to legal entanglement. The mere fact that one is being indicted carries a certain reflection on the character of the defendant. The physicians of the country are in that position today. It is perhaps a strange coincidence that this A.M.A. indictment should have occurred just before the President's Interdepartmental Committee made its recommendations to be submitted to Congress for appropriations for increased government activity in medicine, which in ten years' time will amount to 850 millions of dollars a year. Will not any opposition on the part of the medical profession to this proposal be to a certain extent discredited by the mere fact that we are involved in criminal proceedings?

It is believed that the action against the medical profession is simply a part of a general program on the part of the federal government to break resistance to governmental domination of business and professional groups of citizens. For this reason the progress and outcome of the action are being watched with great interest by various business interests. Many newspapers have come to the defense of the profession editorially.

It is strange that in a country in which the system of free enterprise has been able, in the comparatively short period of 150 years, to establish living conditions far surpassing those anywhere else in the world, there should be such a swing on the part of government to abolish free enterprise through government competition and regimentation in almost every line of activity. Certainly there are enough citizens in our country who value freedom, to influence our legislators irrespective of party designation so they will resist all proposed legislation designed to ruin private enterprise, including the private practice of medicine.

SULFAPYRIDINE IN THE TREATMENT OF PNEUMONIA

THERE has been considerable radio and press publicity regarding the remarkable curative qualities of a new drug related to sulfanilimide and known as sulfapyridine. Physicians are frequently asked about the use of this drug.

The answer is that so far sulfapyridine is not available for general use. According to the requirements of the new Food and Drug Law passed last year by Congress, new drugs cannot be sold until they have been sufficiently tried out experimentally and clinically so that their value has been established, and proper methods of administration and any possible dangers accompanying their use have been determined.

The first reports of the use of sulfapyridine in the treatment of pneumococcis infections, especially pneumonia, which appeared in England, were most optimistic. Reports of its clinical use in St. Louis and Philadelphia which appeared in the *Journal of the American Medical Association* for February 11, 1939, are also favorable. In the same number of the *Journal* appeared a report by Perrin H. Long which constitutes the preliminary statement of the attitude of the Council on Pharmacy and Chemistry regarding this new drug. The Council still considers the use of the drug not yet warranted. Although the reports mentioned are most encouraging the evaluation of new methods of treating pneumonia is difficult. New methods of treating pneumonia have come and gone and one becomes conservative in accepting too readily the reports of new therapeutic measures. The virulence of pneumococcic pneumonia varies so greatly in children and adults and in different localities, that extensive trial is essential before proof can be had that a new drug is entitled to replace, for instance, serum therapy. No one so far can answer the question whether sulfapyridine should replace or be used in conjunction with pneumococcic serum.

Until the profession obtains more complete knowledge regarding sulfapyridine, the well established methods of treating pneumonia which include serum treatment should be continued, although it seems likely that a valuable new drug is about to be available for the treatment of pneumococcic infections.

Distribution of Diphtheria Antitoxin and Toxoid and Smallpox Vaccine by the State Board of Health

Diphtheria Antitoxin.—Diphtheria antitoxin is distributed directly from the offices of the Board and through 250 distributing stations which are in charge of local health officers. Any physician who has immediate use for it may obtain antitoxin at any station. He is required to fill out a receipt and record blank accompanying each package showing its use. Any unused syringes must be promptly returned to the source from which it was obtained. Antitoxin may not be held for possible future use.

Diphtheria Toxoid.—Alum precipitated toxoid (one shot), formalin toxoid (two or three shots), and Schick test material are not distributed through distributing stations but directly from the offices of the Board in the State Office Building, St. Paul. Physicians may obtain any of these biologics in amounts they have immediate use for. Biologics may not be held for possible future use, and any unused vials must be promptly returned.

Toxoid for immunization campaigns or large group immunizations is furnished only when the plans for such immunization or clinic are approved by the respective county or district medical society.

Smallpox Vaccine.—Smallpox vaccine is not distributed through distributing stations but directly from the offices of the Board in the State Office Building, St. Paul. Vaccine cannot be furnished, as is toxoid, to physicians for use in their regular routine office practice. Such restriction is necessary because of the short potency of life of vaccine, the fact that unused or out-dated vaccine cannot be returned to the producer for either credit or exchange for fresh, and particularly because of limited funds.

Vaccine for campaigns and large group immunizations is furnished only when the plans for such immunizations are approved by the respective county or district medical society.

In Memoriam

William Dinwoodie

1854-1938

DR. William Dinwoodie was born October 1, 1854, at Manchester, England, while his Scotch parents, residents of Locherlie, Scotland, were there on a visit.

When fifteen years of age he immigrated with his family to America and settled in Acushnet, Massachusetts. Here he continued his studies. He received his medical degree from the Jefferson Medical School of Philadelphia in 1877.

After practicing for a few years in New Bedford, Massachusetts, Dr. Dinwoodie came to Saint Paul. He joined the Ramsey County Medical Society October 30, 1882, and opened offices on Dayton's Bluff, where he remained until 1915.

In 1886, Dr. Dinwoodie married Pauline Schwartz. They were blessed with three children, a girl and two boys. His wife passed away in 1913 and in 1915 Dr. Dinwoodie moved his office to his daughter's home, where he lived until 1930. At that time his daughter moved to California, and he made an extended trip east before entering the Masonic Home at Savage, Minnesota.

In his younger days Dr. Dinwoodie wrote short stories and poems under the pen name of Edwin I. Wood. These appeared in newspapers and magazines. He served as first president of the Dayton's Bluff Commercial Club. He was a member of the Ancient Landmark Lodge, A. F. and A. M., Minnesota Chapter, I.R.A.M., Osman Temple of the Mystic Shrine, Damascus Commandery, Knights Templar, and was also affiliated with the Odd Fellows, Modern Woodmen of America, and the Scottish Clans. He was a member of the Presbyterian Church and was a republican in politics.

Dr. Dinwoodie died May 12, 1938, following an illness of two months. He is survived by his daughter, Mrs. Burton Benham, a son James of Saint Paul, and a son George C. of Atlanta, Georgia.

Wilmot Edwin Patterson

1882-1939

Dr. W. E. Patterson, for twenty years a practitioner in Westbrook, Minnesota, died following a throat infection, January 15, 1939.

Dr. Patterson was born at Newburgh, Ontario, on October 22, 1882. He graduated from the Newburgh High School and attended medical school at Queens University, Kingston, Ontario, where he received his M.D. degree April 12, 1906. After serving an internship at Bellevue Hospital, New York, he practiced for a year in New York City, and for a year at Rembrandt, Iowa. The years 1910 to 1912 were spent at Westbrook, Minnesota. He then moved to Currie, Minnesota, and in 1918 to Hibbing. In 1919, he returned to Westbrook, where he remained.

In 1914, while at Currie, Dr. Patterson married Isabel Ruth Bragdon, who passed away in 1930. Six children, John, Robert, William, James, Elizabeth Jean, and Phyllis, survive him.

Dr. Patterson was an interested and active member of the Southwestern District Medical Society, the Minnesota State and American Medical Associations. A Presbyterian and a member of the Masonic order, he took an active interest in local public affairs. His was a life devoted to the high ideals of his profession.

David U. Surface

1868-1938

David U. Surface was born August 22, 1868, at Coffeyville, Indiana, and died at his home near Pokegama lake, Dec. 2, 1938. He received his certificate of pharmacy in 1892 and graduated from the Sioux City College of Medicine in 1896. He began the practice of medicine immediately after receiving his diploma in Leeds, Iowa, and later moved to Holly Springs, Iowa, where he operated a drug store in connection with his practice. Later he moved to Castana, Iowa, and then to Nemaha, Iowa.

In 1900 his health compelled him to abandon active practice and he moved to the Black Hills in South Dakota. Physicians were few and far between in that region in those days and he found it impossible to give up medicine. Men would persist in getting shot or otherwise damaged and babies still insisted on being born, and all and sundry needed medical attention.

In 1908 he moved to Ekalaka, Montana, determined to give up the practice of medicine entirely. Here he became acquainted with Dr. Albert S. Sherrill of Camp Crook, S. D., who made regular trips to Ekalaka. A lasting friendship soon developed and Dr. Surface took care of Dr. Sherrill's practice for several years while the latter was attending to his duties as a member of the South Dakota legislature.

When the influenza epidemic of 1918 broke out, the first victim in the little town of Marmarth, North Dakota, was their doctor. Dr. Surface was called immediately and worked day and night with little or no assistance all through the epidemic.

In 1920 he moved to Grand Rapids, Minnesota, where he resided on a farm near Pokegama lake until his death.

Dr. Surface's parents were farmers in Iowa and were financially unable to help him with his education. He left the farm while yet a boy and got work in a drug store, where he commenced his study of pharmacy. When he entered medical school his education was such that he had to study many of the common school branches along with his regular college work. The strain he was under in those days is thought to have been the cause of the early break in his health. He was a partial invalid from 1908 until his death.

Dr. Surface is survived by his wife; one daughter, Mrs. Henry Hegdahl; and two sons, William and Joy, having lost one son in an automobile accident in July, 1938.

An interesting incident occurred while Dr. Surface was in Marmarth. The town had a population of only about 1,000 and only one hotel, where he had engaged a room. Everybody in town knew where to find him so it was impossible to get any rest. One Frank Gibbs owned a hardware and furniture store with undertaking rooms in connection. Seeing that the doctor was about "all in" Mr. Gibbs asked him why he didn't go to bed and get some sleep. The answer was that it was impossible, everyone was clamoring for a doctor. Gibbs said, "You come with me" and he took him to the store and made up a bed in the embalming room. "No one will find you here," and they didn't. He slept the clock around.

THE MARK OF A MAN

A sensible man does not brag . . . You shall not tell me that your commercial house, your partners, or yourself are of importance; you shall not tell me that you have learned to know men; you shall make me feel that; your saying so unsays it. You shall not enumerate your brilliant acquaintances nor tell me by their titles what books you have read. I am to infer that you keep good company by your better information and manners, and so infer your reading from the wealth and accuracy of your conversation . . . The mark of the man of the world is absence of pretensions. He does not make a speech, he takes a low business-tone, avoids all brag, is nobody, dresses plainly, promises not at all, performs much, speaks in monosyllables, hugs his fact. He calls his employment by its lowest name, and so takes from evil tongues their sharpest weapon . . . Men take each other's measure when they meet for the first time—and every time they meet . . . Men do not convince by their argument, but by their personality.

—Ralph Waldo Emerson.

MEDICAL ECONOMICS

**Edited by the Committee on Medical Economics
of the
Minnesota State Medical Association
W. F. Braasch, M.D., Chairman**

THESE PRINCIPLES GOVERN CONTRACT PRACTICE

One of the most important of recent revisions of the Principles of Medical Ethics of the American Medical Association restates specifically the principles which must govern contract practice in all of its forms. Much misunderstanding and contention have developed in many parts of the country as a result of lack of understanding on the part of all concerned of these principles. They were adopted by the House of Delegates of the American Medical Association in 1937 and were explicitly accepted at the recommendation of the Committee on Contract Practice by the House of Delegates of the Minnesota State Medical Association as the measure for acceptance or rejection of all contract practice in Minnesota. They are reprinted here because their importance to every physician demands that he read and be familiar with them.

REVISED PRINCIPLES OF MEDICAL ETHICS OF THE AMERICAN MEDICAL ASSOCIATION—1937

Conditions of Medical Practice

Sec. 2—It is unprofessional for a physician to dispose of his services under conditions that make it impossible to render adequate service to his patient or which interfere with reasonable competition among the physicians of a community. To do this is detrimental to the public and to the individual physician, and lowers the dignity of the profession.

Contract Practice

Sec. 3—By the term "contract practice" as applied to medicine is meant the carrying out of an agreement between a physician or a group of physicians, as principals or agents, and a corporation, organization, political subdivision or individual, to furnish partial or full medical services to a group or class of individuals on the basis of a fee schedule, or for a salary or a fixed rate per capita.

Contract practice *per se* is not unethical. However, certain features or conditions if present make a contract unethical, among which are: (1) When there is a solicitation of patients, directly or indirectly. (2) When there is underbidding to secure the contract. (3) When the compensation is inadequate to assure good medical service. (4) When there is interference with reasonable competition in a community. (5) When free choice of a physician is prevented. (6) When the conditions of employment make it impossible to render adequate service to the patients. (7) When the contract because of any of its provisions or practical results is contrary to sound public policy. The phrase "free choice of physician," as applied to a contract practice, is defined to mean that degree of freedom in choosing a physician which can be exercised under usual conditions of employment between patient and physician when no third party has a valid interest or intervenes. The interjection of a third party who has a valid interest or who intervenes does not *per se* cause a contract to be unethical. A "valid interest" is one where, by law or necessity, a third party is legally responsible either for cost of care or for indemnity. "Intervention" is the voluntary assumption of partial or full financial responsibility for medical care. Intervention shall not proscribe endeavor by component or constituent medical societies to maintain high quality of service rendered by members serving under approved sickness service agreements between such societies and governmental boards or bureaus and approved by the respective societies.

Each contract should be considered on its own merits and in the light of surrounding conditions. Judgment should not be obscured by immediate, temporary or local results. The decision as to its ethical or unethical nature must be based on the ultimate effect for good or ill on the people as a whole.

Direct Profit to Lay Groups

Sec. 5—It is unprofessional for a physician to dispose of his professional attainments to any lay body, organization, group or individual, by whatever name called, or however organized, under terms or conditions which permit a direct profit from the fees, salary or compensation received to accrue to the lay body or individual employing him. Such procedure is beneath the dignity of professional practice, is unfair competition with the profession at large, is harmful alike to the profession of medicine and the welfare of the people, and is against sound public policy.

REPORT ON NORTHWEST REGIONAL CONFERENCE

The Northwest Regional Conference was held in Chicago on February 12. This conference was started in Minnesota some twelve years ago for the purpose of discussing economic problems of medicine. Beginning with a round table discussion in which representatives from Minnesota, Wisconsin and Iowa took part, it has expanded its territory so as to include more than 12 states in the Middle West. More than 150 men were in attendance at the sessions, including ten representatives from Minnesota, presided over by Dr. Carl Vohs of St. Louis. The program included a variety of subjects of current economic interest.

Group Hospitalization Considered

In the first paper, prepared by Major G. Seelig of St. Louis, group hospitalization was considered from a state-wide viewpoint. It is quite remarkable how rapidly group hospitalization has spread throughout the land. Organized medicine was somewhat skeptical about the plan at first, largely because it was feared that medical services would be included in the scheme. However, the public took to the idea from the first, and hospital insurance groups are now organized in most of the larger communities. In many states efforts are now being made to adapt the plan to rural areas. In Missouri, where the movement is well organized, the following measures were adopted to interest the rural districts:

Missouri Procedure

1. A state central committee was formed, in which every county was represented.
2. The farmers were enrolled throughout the state, with the aid of the Farm Bureau.
3. Many difficulties were ironed out, such as objections to the monthly payment, which were overcome by establishing a quarterly payment.

Although the response in urban centers was much better, nevertheless attempts to interest those in the agricultural districts have been quite successful. It is of interest to note that the administrative cost of group hospitalization in Missouri has been greatly lowered and that the average stay in the hospital has been reduced now to 8.5 days. They have been adamant from the start in exempting medical care and in recognizing the independence of the services of anesthetists, pathologists and roentgenologists.

Pennsylvania's Plan

The next paper dealt with the Public Assistance Program for the medically indigent in Pennsylvania, by the highly efficient and intelligent state secretary of the Medical Society of Pennsylvania, Dr. Walter F. Donaldson. The plan is somewhat similar to that adopted in many other states, but differs in that the county welfare committee includes representatives from all the agencies which are involved in caring for the sick. The care of the indigent sick was made responsible to the Public Assistance Department of the state and they turned to the state medical society for guidance. This plan was adopted in most of the counties of Pennsylvania under the guidance of the able secretary and is being successfully carried out to the satisfaction of all concerned.

"Despite Ingratitude"

Said Dr. Donaldson at this meeting: "To the physicians of Pennsylvania and to physicians throughout the nation interested in this great socio-economic medical problem of maintaining quality personalized medical service to indigent wards of the state—no longer to be considered 'charity' patients—we strongly advise patience, integrity and determination. We must apply these virtues to the problem until the taxpayers and their legislative representatives have had time to note that good medical service can not be produced without a fair outlay of money, and may not be maintained under any politically dominated administrative system.

"We need the patience to carry on in spite of defections and criticism within and without our profession. Determination and integrity are essential to the discharge of our definite obligations to the thoroughly matured spirit of our profession to render at all times and to all persons our best service, despite reciprocal misunderstanding or ingratitude. He who does public good for the many may find but few who are truly grateful."

The Pennsylvania plan might well be a model for any state which wishes a similar set-up.

The next paper, on Middletown Modernizes Medicine, by several representatives of organized medicine in Muncie, Indiana, shows to what extent careful organization of the county society can control and facilitate the care of the sick to the mutual satisfaction of all concerned.

School Health

Also of interest was the paper on The Physician's Role in the Public Health Program, by Health Commissioner Theodore Meyer of St. Louis County. This able representative of Public Health has adopted the sane viewpoint that the success of any public health program is dependent upon coöperation with the general practitioner. It was most reassuring to hear him describe the way in which the services of the general practitioner are employed in carrying out the public health program in St. Louis County. The reference of certain duties to the general practitioner and close coöperation between him and the health department has worked out very successfully. He decried the routine methods usually employed in the examination of school children and in its place instituted the plan of transferring their examination to the private office of the family physician. He believes in this way a better and more thorough physical examination can be obtained, rather than the cursory, rapid examination usually given. Confusion frequently resulted in carrying out the advice of the school examiner and physical defects noted by the routine school examination were seldom taken care of. The presence of the parents and discussion with the family physician concerning therapy indicated is essential. Additional advantages of this plan were: (1) parents were educated to have the child pay frequent visits to the physician, (2) the services of an expensive specialist often proved unnecessary, and (3) the percentage of therapy carried out was raised from 3 to 40 per cent.

Public health nurses are trained and instructed to coöperate with the family physician and to follow his instructions.

The success of the treatment of venereal diseases depends entirely on coöperation with the general physician.

"Like a Trout Fly"

Dr. Henry A. Luce of Detroit, president of the Michigan State Medical Society, expressed himself vigorously and picturesquely on the subject of the health security program of President Roosevelt—Michigan is now working on a voluntary health insurance program of its own.

Said Dr. Luce: "The National Health Program is an effort, under disguise, to place organized medicine under a government dictatorship.

"It is like a trout fly," he said, "beautiful to look at and it attracts the fish; but it has a hook in it."

In one place in the President's message, Dr. Luce pointed out, the government's responsibility in a federal health program was declared to be financial and technical, the creation and direction of programs being left to the states.

If the Government Wants It, Too

In another place it was pointed out that federal grants in aid would only be made to programs meeting federal approval.

"In other words," said Dr. Luce, "you can have any medical system you want, provided it is what the federal government wants.

"The recommendations of organized medicine have been ignored in the formulation of the federal program for expansion of medical care. Propaganda has been released to discredit the medical profession.

"If the forces that are now seeking government-controlled medical care continue unchecked, they will lead direct to a dictatorship that is communistic in thought.

Concerning Possible Dangers

Under the title of Supplementary Arrangements for Medical Care, Dr. R. G. Leland of the Bureau of Medical Economics of the A.M.A. made some very interesting observations concerning recent developments in the field of sickness and hospital insurance. He called attention to some of the possible dangers involved and his counsel will bear careful study by members of every state or county society adopting these plans. His remarks will not be discussed further here, since Dr. Leland is planning to talk on a similar subject to the Conference of County Officers in the near future.

Medical Survey

I was asked to submit a summary on the progress of the Survey conducted by the A.M.A. on the need and supply of medical and hospital care. Since the reports are far from complete and the data are in the process of being assembled preparatory for a final report to the A.M.A. in May, it was impossible to give any conclusions as to the final results. However, there were several points which were outstanding. In the first place, the percentage of physicians who appreciated the importance of the Survey and who coöperated in carrying it out unfortunately was comparatively low.

Physicians Lagged

It is quite apparent that the majority of physicians failed to appreciate the importance of the Survey and its practical significance. It is estimated that the returns from Form 1 which was filled out by doctors and dentists will be available from only about twenty per cent of the membership of the A.M.A. In contrast, the returns from the other forms filled out by allied agencies will average better than 60 per cent and in several states they will be almost 100 per cent complete. Some objections were made to filling out the three forms of 1F with references made to useless bookkeeping. In the Bureau of Economics are copies of 59 blanks which must be filled out at the end of each day by the physician in France if he wishes to collect his fees, and there are a greater number in Germany. Nevertheless, it is believed that there will be enough returns by March 1, when the final summaries will be made in the Bureau of Economics, so that a fair appraisal of the status of medical care in the U. S. will be available.

Estimate Exaggerated

One fact stands out rather prominently—the much quoted estimate made by Federal Health authorities to the effect that there are forty million people in the United States who lack adequate medical care is the wildest exaggeration. Forty thousand people would be nearer the truth, and but few of these would be barred from medical care if they cared to have it. There is considerable difference in the various sections of the country in available health services. In certain sections of the South and in some of the sparsely settled areas of western states, current economic conditions have made medical care unsatisfactory.

In most of the country, instances of failure in securing medical care have been amazingly few. The financial burden in certain groups seemed to be the greatest problem noted by many physicians and allied agencies.

Study Invaluable

Medical societies everywhere are endeavoring to solve this problem and will do so without federal interference. A large number of physicians expressed the desire for some form of voluntary sickness insurance controlled by organized medicine. The Survey should prove to be invaluable in giving for the first time fairly complete appraisal of the status of medical care and its facilities in the counties and states. This should serve as a guide as to ways for improvement of our present methods. Another advantage gained should be an increased coöperation in future. Certain it is that more surveys in the future will be necessary to progress.

W. F. Braasch, M.D.

POPULAR NEW PROGRAM

The Coördinated Medical and Public Health Program of the Minnesota State Medical Association is now three months old and some 500 requests for packets have already been received at the state office.

Three bulletins on the subjects of the month have been sent out to each member; the pneumonia bulletin in January, the pediatrics bulletin in February and the bulletin on degenerative diseases in March. Speakers have been secured for a number of medical societies on the subject and also for parent-teacher groups and others. A special series of newspaper articles has been sent to Minnesota newspapers for each month and the weekly radio broadcasts by Dr. W. A. O'Brien have been selected especially to further the program. A program of this type gathers momentum as it goes and, judging by its early popularity, the new program should be one of the most valuable activities ever carried on by the state association.

The regular News Letter from the state office which went, previously, only to county officers and committee members, is now being sent with the bulletin of the month, also, to each member.

News notes from county societies concerning meetings or other undertakings will be welcomed for this News Letter which is designed especially to disseminate organization news and which, it is hoped, will be read by every member.

DO WE WANT A JOB HOLDER?

Two recent editorials from the *Windom Reporter* (Minn.) are typical of the reservations which many Minnesota editors expressed with regard to President Roosevelt's national health program.

Paragraphs from each follow:

> "Roosevelt's latest appeal for popularity through federal care for the ills of mankind takes the line of socialized medicine. The American Medical Association is opposed to this scheme for a great many very good reasons, reasons which every voter should consider. Not the least of these reasons is that it will have a tendency to arrest and discourage advancement in medical science. Beyond that, there is the political patronage slant, the fact that in countries where it has been tried there is more sickness and fewer new and successful treatments discovered . . . The question is do we want to select our own family doctor or just a political job holder?"

With Special Alarm

> "Washington correspondent, Paul Mallon, says that Roosevelt's appeal to the dear people in the form of socialized medicine (a salaried doctor in place of your family doctor) was blown out of a window when it came before Congress. It didn't get as far as fixing world finance, the workmen's pay envelope, the price of railroad ties and a lot of other things. Of course if it had got through, we could expect with it an alarm clock for each person so arranged as to give a special alarm to wake the patient up when it was time for him to take the government medicine."

NOT A SUBSTITUTE

There can be little disagreement on certain fundamental objectives in regard to medical care. The medical profession agrees with all her agencies on the importance of the following objectives: the provision of good medical care for all the people; the development of comprehensive preventive and public health services; the development of appropriate measures to combat specific health problems; and a continuous, orderly improvement of the distribution of medical services and hospital facilities, both by geographic and economic divisions.

The medical profession would be the "last to deny the existence of medical needs" in the United States. Its whole mission has been to fulfill those needs, and it has always sought to meet every need at is arises by the development of appropriate medical services. The profession, however, cannot be blind to the fact that there are other unfulfilled needs, especially such as relate to food, clothing and housing, which are often as essential to the preservation of health as is medical care. It is impossible to isolate medical care from these other needs either with regard to the preservation of health or in the formulation of a health program; neither can medical care be looked upon as a substitute for such other essentials.

—*Bronx County Medical Bulletin.*

TEN DON'TS IN THE FRACTURE CASE

(Monthly editorial prepared by the Medical Advisory Committee)

That you may avoid malpractice litigation and its inconvenience, your Medical Advisory Committee submits the following DON'TS: IN FRACTURE CASES.

1. Do not attempt to treat a sprain or fracture without an x-ray examination.
2. Do not reduce a fracture with misplacement without some type of an anesthetic.
3. Do not reduce a fracture without competent assistance.
4. Do not fail to tell the patient the condition you are trying to overcome.
5. Do not apply a cast or splint without advising the patient of the symptoms of impaired circulation.
6. Do not fail to advise and insist on hospital care if you deem it necessary.
7. Do not neglect to see the patient often enough. Better many times too many than once too few.
8. Do not forget to advise the patient of the damage to soft parts and the possible result of this damage to function.
9. Do not let him forget that complete coöperation is expected by you during treatment and that only through such coöperation can best results be obtained.
10. Do not fail to make detailed records which should include history of accident, physical and laboratory findings—those present at time of examination and treatments—x-ray findings, dates of services rendered, splints and other materials used, advice given pa-

tient and information as to who may have heard this conversation. In fact, do not think any incident or happening too insignificant to warrant recording. Then file them carefully and permanently.—B.J.B.

MINNESOTA STATE BOARD OF MEDICAL EXAMINERS

License of Minneapolis Physician Revoked

In the Matter of the Revocation of the License of George Frederick Lemke, M.D.

Following a hearing held before the Minnesota State Board of Medical Examiners on February 11, 1939, the license to practice medicine and surgery held by George Frederick Lemke, M.D., 512 Pence Bulding, Minneapolis, was revoked. Dr. Lemke was found guilty by the Medical Board of procuring, aiding and abetting a criminal abortion on a twenty-two year old Saint Paul girl. The Board also found Dr. Lemke guilty of conduct unbecoming a person licensed to practice medicine and detrimental to the best interests of the public in connection with the same case.

The girl, employed in the diet department of a Saint Paul hospital, was found dead on a table in Dr. Lemke's office on December 10, 1938. The evidence before the Board disclosed she paid Dr. Lemke $50 for an abortion; that she died while the abortion was being performed by Dr. Lemke. There was also testimony that Dr. Lemke performed from fifteen to twenty-five abortions per month; that his charges ranged from $50 to $300.

The records of the Medical Board show that Dr. Lemke was indicted for abortion in 1912 but was not tried until 1914 when he was found not guilty, in the District Court at Minneapolis. Dr. Lemke was also indicted in Federal Court in 1913 in Minneapolis charged with sending information through the mails on abortion. He was found guilty, then granted a new trial and finally acquitted.

Dr. Lemke was born in Saint Paul in 1879 and graduated from the College of Physicians and Surgeons at Baltimore in 1906. He was licensed in Minnesota in 1908 on reciprocity with New Jersey where he was licensed in 1907. Dr. Lemke was also licensed in New York in 1907.

INTRANASAL MEDICATION

Recently Walsh and Cannon (Ann. Otol., Rhin. and Laryng., 47:579, Sept., 1938) reported that the intranasal administration of oily preparations, when given in large total amounts and over a long period to normal rabbits free from upper respiratory infections, seemed to initiate lesions in the lungs which could be demonstrated in roentgenograms. These investigators found that isotonic saline solutions containing such vasoconstrictors as ephedrine hydrochloride and neosynephrin hydrochloride did not cause pulmonary damage after intranasal instillation in normal rabbits. The observations of these workers and the reports of others point to the potential dangers of intranasal medication and to the tentative conclusion that the only completely safe intranasal medicaments are weak saline solutions of appropriate vasoconstrictors. (J.A.M.A., Nov. 5, 1938, p. 1770.)

OF GENERAL INTEREST

Dr. O. F. Mellby is the newly named chief of staff of Mercy Hospital, Thief River Falls. Trustees of the hospital appointed him at their meeting on February 14.

* * *

Dr. and Mrs. M. Vik, who have been in the South for the past month and a half, returned recently to their home in Onamia. While away, Dr. Vik studied in New Orleans.

* * *

Dr. Karl C. Wold has announced the removal of his offices to 515 Lowry Medical Arts Building, Saint Paul, and his association with Dr. Robert W. Holman, in the eye, ear, nose and throat specialty.

* * *

For an indefinite period of time, Dr. D. T. Schuele, of the Gamble Clinic at Albert Lea, will include in his practice Emmons, Minnesota, and vicinity. He succeeds Dr. R. T. Trombley, who left recently for New Mexico.

* * *

Dr. Carl Coombs, formerly associated with Dr. R. C. Radabaugh of Hastings, Minnesota, has taken over the practice of Dr. Leila Gorenflo at Cass Lake. Dr. and Mrs. Coombs moved to their new home the first week of February.

* * *

On February 5, Dr. Leonard Johnston initiated his medical and surgical practice in Slayton, Minnesota, by opening offices in the Weck Building there. Dr. Johnston formerly practiced in Minneapolis. He and Mrs. Johnston are now making their home at Slayton.

* * *

Dr. P. E. Kierland, of Alexandria, Minnesota, has been appointed county coroner to fill the vacancy in this office occasioned by the death of Dr. J. A. McCabe. Dr. Kierland was appointed at the meeting of the Douglas County Commissioners on Tuesday morning, February 7.

* * *

On Tuesday, February 14, Miss Mary Loretta Lawler, daughter of Mr. and Mrs. Martin J. Lawler, of Rochester, became the bride of Dr. Walter F. Kvale, a fellow in the Mayo foundation. Upon returning from their wedding trip, Dr. and Mrs. Kvale will make their home in Rochester.

* * *

Dr. E. E. Novak of New Prague, former president of the Minnesota School Board Association, has been elected a member of the Board of Regents of the University of Minnesota, by the state legislature. Dr. Novak represents the second congressional district. His term expires in February, 1943.

* * *

Dr. Ludvig Hektoen, Executive Director of the National Advisory Cancer Council, U. S. Public Health Service, will present the Annual Minnesota Cancer Institute Lecture on April 17, 1939. Dr. Hektoen will speak on "Advances in the Knowledge and Control of Cancer."

* * *

Dr. Irvine McQuarrie, Professor and Head of the Department of Pediatrics, University of Minnesota, will speak on "The Significance of Inorganic Metabolism in Diabetes" at a joint meeting of the Wayne County Medical Society and the Detroit Diabetes Association on February 13, in Detroit.

* * *

Dr. Henry Porter Johnson, of Fairmont, Minnesota, veteran of half a century in medicine, celebrated his 84th birthday on the 3rd of February. The "Grand Old Man of Medicine," as he is affectionately called by people of his community, is still vigorous and active. He goes to his office daily and still makes calls on patients.

* * *

Dr. Arthur E. Hertzler of the Hertzler Clinic, Halstead, Kansas, and author of "The Horse and Buggy Doctor," will present the Sixth Annual Clarence E. Jackson Lecture on Thursday evening, March 16, 1939, in the Northrop Memorial Auditorium. The subject of Dr. Hertzler's address will be "The Morphology of the Thyroid Gland."

* * *

On February 24, Dr. E. T. Bell, Professor and Head of the Department of Pathology, University of Minnesota, will deliver the Christian Fenger Lecture of the Chicago Pathological Society and Institute of Medicine at the Palmer House in Chicago. Dr. Bell will speak on the pathogenesis of glomerulonephritis, including lipoid nephrosis.

* * *

Dr. George W. Clifford, of Osakis, recently has joined partnership with Drs. A. D. Haskell and P. E. Kierland, of Alexandria. He is filling the vacancy occasioned by the departure of Dr. R. W. Steube, who has been associated with Dr. Haskell and Dr. Kierland for the past few years. Dr. Steube is leaving Alexandria to take a postgraduate course in surgery.

* * *

Dr. Owen H. Wangensteen, Professor and Head of the Department of Surgery, University of Minnesota, gave the fifteenth Lewis Linn McArthur Lecture of the Frank Billings Foundation on January 27 at the Institute of Medicine of Chicago. Dr. Wangensteen spoke on "The Genesis of Appendicitis in the Light of Functional Behavior of the Vermiform Appendix."

* * *

Human convalescent serum is now available for the prevention or treatment of measles, scarlet fever, whooping cough and mumps, according to a recent announcement of the Human Serum Laboratory of the University of Minnesota.

Serum will be furnished at the standard price set by the American Human Serum Association.

* * *

Dr. Frederick C. Warnshuis, president of the American Medico-Legal Association, with headquarters at 137 Newbury Street, Boston, is desirous of receiving the names and addresses of Doctors in Medicine who have also received degrees from accredited law schools and have been admitted to the bar. All such are requested to submit their names and data regarding past and present medical and legal activities to him.

* * *

For the fifth consecutive year, the psychiatric staff of the Menninger Clinic, Topeka, Kansas, will offer a week's postgraduate course in *Neuropsychiatry in General Practice,* April 17-22. This practical presentation of dynamic psychiatry through lectures and case presentations has been attended by physicians from nineteen states in the past four years. Enrollment is limited to thirty. Address inquiries to Dr. Robert P. Knight, Chairman.

* * *

With talks before the Royal Society of Medicine, London, and before the Gesellschaft der Aerzte, Zurich, in prospect, Dr. J. G. Love sailed with Mrs. Love from New York for Europe on Saturday, February 11. While Dr. and Mrs. Love are touring the continent, Dr. Love will make a special point of visiting clinics in Italy, Switzerland, Belgium, Holland, the Scandinavian countries, the British Isles, and France.

* * *

The Samuel D. Gross Prize of the Philadelphia Academy of Surgery, consisting of $1,500, is again being offered for the best original essay, not to exceed 150 pages, on some subject in Surgical Pathology or Surgical Practice. The essay must be written by one author, an American citizen, and should be sent to the Trustees of the Samuel D. Gross Prize, of the Philadelphia Academy of Surgery, care of the College of Physicians, 19 South 22nd Street, Philadelphia, Pennsylvania, before January 1, 1940.

* * *

Plans are under way for widespread use of a new visual educational method known as "isotype" in the Minnesota campaign against tuberculosis. Charts and booklets in which important information on health are graphically presented by use of symbols or stickmen will be distributed throughout the state in 1939 as far as Christmas Seal funds permit, according to an announcement made by Dr. E. A. Meyerding, Executive Secretary of the Minnesota Public Health Association.

"Tuberculosis Spreads in the Household"; "Protecting One Protects Many"; "Tuberculosis Germs Are Passed from Person to Person in Many Ways"; "Tuberculin Tests and X-ray Discover the Infected and the Sick," are a few of the messages strikingly presented by stickmen on the charts.

Developed by Dr. Otto Neurath of the International Foundation for Visual Education, of the Hague, Holland, inventor of isotype, with the coöperation of the National Tuberculosis Association, the charts represent the most modern approach to the educational problem.

REPORTS and ANNOUNCEMENTS

MEDICAL BROADCAST FOR MARCH

The Minnesota State Medical Association Morning Health Service

The Minnesota State Medical Association broadcasts weekly at 11:00 o'clock every Saturday morning over Station WCCO, Minneapolis (810 kilocycles or 3702 meters) and Station WLB, University of Minnesota (760 kilocycles or 395 meters).

Speaker: William A. O'Brien, M.D., Associate Professor of Pathology and Preventive Medicine, Medical School, University of Minnesota. The program for the month will be as follows:

March 4—Diabetes Mellitus
March 11—Heart Disease
March 18—Hardening of Arteries
March 25—Artificial Dentures

AMERICAN ASSOCIATION OF OBSTETRICIANS, GYNECOLOGISTS AND ABDOMINAL SURGEONS

The American Association of Obstetricians, Gynecologists and Abdominal Surgeons announces that the annual Foundation Prize for this year will be $100.00. Those eligible include only (1) interns, residents, or graduate students in Obstetrics, Gynecology and Abdominal Surgery, and (2) physicians (M.D. degree) who are actually practicing or teaching Obstetrics, Gynecology or Abdominal Surgery.

Competing manuscripts must (1) be presented in *triplicate* under a nom de plume to the Secretary of the Association before June 1, (2) be limited to 5,000 words and such illustrations as are necessary for a clear exposition of the thesis, and (3) be typewritten (double-spaced) on one side of the sheets, with ample margins.

The successful thesis must be presented at the next annual (September) meeting of the Association, without expense to the Association and in conformity with its regulations.

For further details, address Dr. James R. Bloss, Secretary, 418 11th Street, Huntington, W. Va.

AMERICAN ASSOCIATION FOR THE STUDY OF GOITER

The next annual meeting of the association will be held in Cincinnati, Ohio, May 22, 23, 24, 1939. Dry and operative clinics, as well as lectures, will occupy the three-day session.

The Van Meter Prize Award of $300 and two honorable mentions for the best essays concerning original work on goiter problems will be awarded at the meeting. Information regarding submission of papers, which must be sent in before April 15, may be obtained from Dr. W. Blair Mosser, 133 Biddle Street, Kane, Pennsylvania.

NORTH DAKOTA STATE MEDICAL ASSOCIATION

Tentative Program of the Annual Meeting, Fargo, N. D., May 8, 9, and 10, 1939

Fargo Auditorium
May 8, 1939
Morning Session

Diagnosis and Management of the Surgical Gallbladder.—Dr. E. M. Jones, St. Paul, Minn.

Paper on Obstetrics.—Dr. J. H. Moore, Grand Forks, N. D.

Paper on Obstetrics.—Dr. Ralph A. Reis, Chicago, Ill.

Problems of Latent and Wassermann-Fast Syphilis.—Dr. H. E. Michelson, Minneapolis, Minn.

Afternoon Session

Dermatology for The General Practitioner.—Dr. H. E. Michelson, Minneapolis, Minn.

New Methods in The Treatment of Gonorrhea in the Male and the Female.—Dr. L. W. Larson, Bismarck, N. D.

Diagnosis and Treatment of Eye, Ear, Nose and Throat Conditions.—Dr. A. D. McCannel, Minot, N. D.

Proctology.—Dr. L. A. Buie, Rochester, Minn.

May 10, 1939
Morning Session

Emergency Orthopedic Problems.—Dr. H. J. Fortin, Fargo, N. D.

Surgical Paper.

Pediatric Paper. (Author and subject to be announced later.)

Cardiac Emergencies.—Dr. F. J. Hirschboeck, Duluth, Minn.

Afternoon Session

Tuberculosis.—Dr. G. A. Dodds, San Haven, N. D.

Hypertension.—Dr. S. Marx White, Minneapolis, Minn.

Diagnosis and Treatment of Gastrointestinal Hemorrhage.—Dr. F. J. Hirschboeck, Duluth, Minn.

STATE MEETING

Any member who has original scientific work to exhibit is urged by the Committee on Scientific Assembly to communicate immediately with state headquarters of the Minnesota State Medical Association.

An unusually fine scientific exhibit is now being arranged for the 86th Annual Meeting which is to be held at the Minneapolis Auditorium May 31, June 1 and 2, and special effort is being made to secure as many exhibits as possible from individual physicians. Following a precedent of many years, the Southern Minnesota Medical Association will present a gold medal for the best such individual exhibit to be presented at the meeting. The winner will receive his award at the annual banquet scheduled for Thursday, June 1, at the Curtis Hotel.

The most varied and extensive meeting ever held by the association is planned for this Minneapolis gathering. A public health exposition which will occupy the entire ground floor of the Auditorium is planned for the three days of the scientific meeting and the following Saturday, June 3, as well. This show will be held under the sponsorship of the association and with the close coöperation of the State Department of Health, the University of Minnesota, and the Minneapolis city health department.

The first two days, Wednesday and Thursday, will be devoted exclusively to scientific papers and discussions with round table luncheons each day on special subjects. Leaders for these luncheons, which are to be limited in attendance to twenty for each one, will be drawn from visiting speakers and members who are leaders in their respective specialties.

The second Congress of Allied Professions will occupy the entire program for Friday, with several national leaders in public health and welfare as speakers, and a frank discussion of current economic and social problems as they affect health and medicine, planned. Hospital administrators, nurses, dentists, pharmacists and others will be invited to attend this meeting.

Business sessions of the Council and House of Delegates will begin on the afternoon of Tuesday, May 30, Decoration Day.

MAYO FOUNDATION CLINICAL WEEK

A special program of lectures and demonstrations in surgery and medicine will be held under the direction of The Mayo Foundation from April 11 to 15, inclusive. Mornings will be devoted to surgical and medical clinics. In the afternoons and evenings presentations of various surgical subjects will be made and symposiums will be conducted on heart disease, arthritis, gynecology, gastro-enterology, oxygen therapy, pneumonia and bronchial asthma. Visiting physicians are invited to attend.

CENTER FOR CONTINUATION STUDY

The Center for Continuation Study of the University of Minnesota in coöperation with the Minnesota State Medical Association announces a series of six-day postgraduate courses in special fields of medicine. The program will be held in the special building devoted to postgraduate education for all professional fields. This building also serves as a residence hall for professional groups while in attendance at the University.

Subjects will be Nervous and Mental Diseases, March 13-18; Diseases and Injuries of Bones and Joints, March 13-18; Diagnostic Roentgenology, March 27-April 1; General Surgery, April 10-15; Diseases of Blood and Blood-Forming Organs, April 17-22; Obstetrics, May 1-6; Gastroenterology, May 8-13. The tuition for each course will be $25.00. Room and Board may be secured for $16.00. Physicians from outside of Minnesota are admitted on the same basis as residents.

For further information, write to J. M. Nolte, Director Center for Continuation Study, University of Minnesota, Minneapolis, Minnesota.

AMERICAN COLLEGE OF SURGEONS

A Sectional Meeting of the American College of Surgeons will be held at Winnipeg, Manitoba, March 29, 30, 31. Fellows of the College from Minnesota, South Dakota, North Dakota, Saskatchewan, Alberta, Western Ontario and Manitoba will meet at the Fort Garry Hotel, Winnipeg. The Executive Committee on local arrangements is composed of J. A. Gunn, M.D., O. S. Waugh, M.D., G. S. Fahrni, M.D., J. D. McQueen, M.D., C. W. Burns, M.D., W. A. Gardner, M.D., R. B. Mitchell, M.D.

A meeting on Health Conservation will be held at Grace Church on March 31, for the public.

AMERICAN COLLEGE OF PHYSICIANS

The twenty-third annual session of the American College of Physicians will be held in New Orleans, March 27-31, 1939. An extensive program consisting of scientific addresses and round table discussions will occupy four and a half days interspersed with entertainment features.

Dr. William J. Kerr of San Francisco is president and Dr. O. H. Perry Pepper of Philadelphia, president-elect. E. R. Loveland, 4200 Pine Street, Philadelphia, is the executive secretary of the College.

BLUE EARTH VALLEY SOCIETY

The Blue Earth Valley Medical Society, comprising Faribault and Martin Counties, met at Fairmont January 26, 1939. Twenty members were present at dinner at the Fairmont Hotel and after a short business meeting a program on pneumonia was given.

Dr. F. A. Gunlaugson, District Health Officer of Mankato, gave a talk on pneumonia serum and Dr. Walter M. Boothby of the Mayo Clinic gave a demonstration of the new oxygen mask and spoke on its usefulness in the treatment of disease.

The following are officers for 1939: Dr. H. H. Russ, Blue Earth, president; Dr. P. W. Demo, Wells, vice president; Dr. W. C. Chambers, Blue Earth, secretary-treasurer; and Dr. R. C. Hunt, Fairmont, delegate to the State Association.

GOODHUE COUNTY SOCIETY

The Goodhue County Medical Society held a business meeting on Friday, January 20, at which Dr. Grant F. Hartnagel was elected president. Dr. A. W. Jones was re-elected vice president, and Dr. E. H. Juers was re-elected secretary and treasurer.

WASHINGTON COUNTY SOCIETY

The Washington County Medical Society held its regular monthly meeting Tuesday evening, February 14, in the Stillwater club rooms. The meeting was devoted entirely to the discussion of medical care of indigents, welfare work and hospitalization. Two county commissioners, two hospital board members and one welfare official took part in the discussion.

◆ WOMEN'S AUXILIARY ◆

Mrs. W. B. Roberts, Minneapolis, *President*
Mrs. E. V. Goltz, 2259 Summit Avenue, Saint Paul, *Publicity Chairman*

The Executive Board of the Women's Auxiliary of the Minnesota State Medical Association met February 1 at the Women's City Club, Saint Paul, with Mrs. Wm. B. Roberts, the president, presiding. Mrs. E. M. Hammes of Saint Paul was the social chairman. Despite the weather conditions the meeting was well attended. A most interesting report of the National Board meeting was given by Mrs. Roberts. After hearing reports from the various chairmen and the county presidents, plans were discussed for the annual meeting which will be held in Minneapolis the last of May and the first of June. A cordial invitation to all members to attend this meeting was extended by the Hennepin County president, Mrs. R. R. Cranmer. A nominating committee was appointed to complete a slate for the annual election of officers in May. Serving on this committee are Mrs. B. F. Davis of Duluth, Mrs. Charles Bolsta of Ortonville, Mrs. Martin Nordland of Minneapolis, Mrs. A. E. Nichols, Saint Paul, and Mrs. J. W. Stuhr of Stillwater. At the luncheon meeting the group had the pleasure of hearing Dr. George A. Earl, president of the Minnesota State Medical Association, who gave a most inspiring talk on "The Medical Outlook." Mr. F. Manley Brist of the association's legislative department also spoke. A number of out-of-town members braved the storm and were present, including Mrs. John F. Norman, past president, Crookston; Mrs. A. C. Baker, president-elect, Fergus Falls, Mmes. J. W. Josewski, E. S. Boleyn and J. W. Stuhr, Stillwater; Mrs. Charles Bolsta, Ortonville. From Duluth came Mmes. Malcolm G. Gillespie, Thomas O. Young, Benjamin F. Davis and F. J. Elias. Mrs. Theodore Satersmoen attended from Pelican Rapids. Shakopee was represented by Mmes. N. S. Dungay, H. E. Wunder and P. M. Fischer. Mrs. James Blake, Hopkins, and Mmes. Clarence Moberg and R. N. Gunderson came from Lake Park. Minneapolis and Saint Paul were well represented.

* * *

The Hennepin County Auxiliary heard Dr. J. M. Hayes discuss "Socialized Medicine" at their meeting, February 3, which was held in the lounge on the twentieth floor of the Medical Arts Building. Mrs. Hamlin Mattson represented the hospitality committee and was assisted by Mrs. Ernest Meland and Mrs. Rollin E. Cutts.

* * *

The Stearns-Benton Counties Medical Auxiliary met at the home of Mrs. Joseph B. Gaida in St. Cloud on February 9 for its February meeting and pot-luck supper. The spring flowers used throughout the rooms were in direct contrast to the wintry night outside. The valentine motif was used in decorations and in the menu. Despite the weather, there were nineteen present. Mrs. T. N. Fleming, the president, announced that *Hygeia* had been placed in eleven high schools and grade schools by the auxiliary. Money for this project is being raised by a series of benefits. So far, one bridge benefit has been given at the home of Mrs. Charles Donaldson in Foley with Mrs. H. B. Clark of St. Cloud assisting with the arrangements. Following the meeting, Mrs. R. N. Jones of St. Cloud gave a delightful book review on "The Citadel" by A. J. Cronin, after which the book was discussed by the members. The March meeting will take place at the home of the secretary, Mrs. P. E. Barringer, in St. Cloud.

* * *

The Washington County Medical Auxiliary held its regular monthly meeting Tuesday afternoon, February 14. The hostess, Mrs. J. W. Stuhr, entertained nine members and two guests at a valentine party. The afternoon lunch was preceded by the business meeting, followed by a short discussion led by Mrs. E. Sydney Boleyn on the perils of government-controlled medicine. Mrs. C. E. Proshek, wife of a Minneapolis physician and a Czechoslovakian, told of some of her unhappy experiences under that regime in her native country.

* * *

A meeting of the West Central Auxiliary was held December 15 at Morris, Minnesota. Dinner was served at 6:30 p. m. at the Merchants Hotel, with nine members present. After dinner, the members held their business meeting at the home of Mrs. F. W. Behmler. Mrs. I. L. Oliver of Graceville, the president, presided. Mrs. Ewing gave a splendid report on the state convention held in Duluth and Mrs. Bolstad gave a report on the State Executive board meeting held in Minneapolis. It was voted to have *Hygeia* placed in the school libraries, through the Auxiliary in Ortonville, Graceville, Wheaton, Clinton and Morris. Mrs. Bergen was elected chairman for the March meeting at which socialized medicine will be discussed.

* * *

The state president, Mrs. Wm. B. Roberts of Minneapolis, will attend the meeting of the West Central Auxiliary, March 8, and will also be a guest at the March 14 meeting of the Washington County Auxiliary to be held in Stillwater. Mrs. Roberts was a visitor in Brainerd, January 28, when she was the house guest of Mrs. J. A. Thebes, Sr., and attended the Auxiliary meeting there on that day.

PROCEEDINGS OF THE MINNESOTA ACADEMY OF MEDICINE

Meeting of January 11, 1939

The regular monthly meeting of the Minnesota Academy of Medicine was held at the Town and Country Club on Wednesday evening, January 11, 1939. Dinner was served at 7 o'clock and the meeting was called to order by the president, Dr. C. B. Drake, at 8:10 p. m.

There were forty-three members and three guests present.

Minutes of the December meeting were read and approved.

Dr. Thomas S. Roberts, chairman, announced that the Executive Committee had audited the treasurer's annual report, found it correct, and moved it be accepted. Motion seconded and carried.

Dr. Drake reported the recent death of Dr. Chester M. Carlaw on January 7, and appointed Dr. Herbert Jones to draw up a suitable memorial to Dr. Carlaw for presentation to the Academy.

Dr. R. T. LaVake, retiring president, announced to the Academy a bound volume, to be used as a reference book, compiled over the past twelve or thirteen years by Miss Crever. This covers the first fifty years of the Academy and contains information about charter members, past presidents, elections, officers, dates and places of meetings, and includes programs, where the proceedings and papers may be found published, et cetera, also an author index of all papers, theses, addresses, and most of the memorials and case reports presented in those fifty years—in fact, all available data she could gather from the published proceedings and the old minute books of the Academy; also a supplement containing a copy of the minutes of a Minneapolis medical organization known as The Unity Club organized in October, 1884, apparently the forerunner of the Minnesota Academy of Medicine, the membership of which apparently was the basis for the Minneapolis part of the Academy in October, 1887. This book is intended to be kept by the secretary of the Academy for reference and passed on to his successors.

Dr. La Vake read the Preface of the book. Dr. Harry P. Ritchie, under whose secretaryship Miss Crever began reporting the meetings in 1921, then made some remarks and proposed the following motion:

I move, Mr. President, that the Secretary be instructed to call this to the attention of the Executive Committee, not only with the idea of accepting and acknowledging this wonderful contribution, but to determine an honorarium which will be fitting and appropriate for Miss Crever's years of service to this Academy. Motion seconded.

Dr. C. D. Freeman then made a motion that a committee consisting of Dr. Ritchie, Dr. La Vake—and they to choose a third man—decide what she should receive as an honorarium.

It was suggested, there being a motion already before the Academy, that Dr. Freeman's motion be made as an amendment to the motion. Dr. Freeman assented, and the amendment was seconded and, upon vote, carried. The motion, as amended, was then seconded, and, upon vote, carried.

The scientific program followed.

THE CESAREAN PROBLEM

R. T. La Vake, M.D.

Minneapolis

Dr. R. T. La Vake, retiring president, then read his Presidential Address on the above subject, and showed numerous lantern slides of charts and tables. (To be published in full in Minnesota Medicine.)

Synopsis

During the past twenty-five years obstetrics has made great advances potential for the reduction of maternal mortality. Among these advances are: perfection of roentgen-ray technic, making possible the more accurate diagnosis of pelvic deformity and disproportion; improved treatment of pernicious vomiting by hydration, high carbohydrate therapy and vitamin B administration; the perfection of prenatal care, which should bring women to labor in better general physical condition and with the birth canal uninfected, and has made more widespread the earlier detection of approaching preëclamptic toxemia; improved treatment of preëclamptic toxemia, making the accession of eclampsia less frequent; the masking of attendants upon parturient women to avoid droplet infection; perfection of blood transfusion technic which has increased our command over the results of hemorrhage, shock and infection; incontrovertible evidence of the lower mortality rate of the low cervical section as compared with the classical operation; and the increased safety of local anesthesia as compared with inhalation anesthesia in cesarean section, especially when toxemia exists.

In spite of all these advances, the general maternal mortality rate has been reduced very little. This fact is rendered more striking when we consider that we have seen a narrowing of those areas previously inaccessible to medical attention; that we have seen tremendous educational campaigns which must have reduced the factors of public ignorance and apathy; that we have witnessed the wide extension of social service and public health nursing and the extension of special facilities for maternal care, including personnel and material, in nearly every town of appreciable size, and, year by year, though obstetrical education has had its faults and limitations, at least facilities for teaching have continuously improved.

A study of innumerable investigations as to the cause for the great discrepancy between what one would reasonably expect in the lowering of general maternal mortality and the facts as proved by statistics, insistently points to the widespread increase of unnecessary and often contraindicated operative interference as the outstanding cause. Prominent among such operative interferences, stands cesarean section.

The average incidence of cesarean section is ten times greater than it was twenty-five years ago. This increase in incidence has not been offset by a proportional decrease in average operative mortality.

A statistical study is made of results, indicating the correct uses of cesarean section and factors that influence the results. It is suggested that the problem of errors and abuses in cesarean section can best be solved by the punctilious carrying out of the hospital standard 3-b adopted by the American College of Surgeons in 1918, namely:

> "That the medical staff review and analyze, at regular intervals, their clinical experience in the various departments of the hospital, such as medicine, surgery, and obstetrics and the other specialties; the medical records of patients, free and pay, to be the basis for such review and analysis."

Such analysis in regard to cesarean section should bring out the following data:

1. Was there a consultation and, if not, why?
2. What was the indication?
3. If the indication was pelvic contraction, what were the findings of pelvimetry, Munro Kerr maneuver, or x-ray?
4. Was the child dead or alive at the time of operation?
5. Did x-ray give any evidence of deformity (hydrocephalus, et cetera)?
6. Was the section elective, or after a test of labor and how long a test?
7. Were the membranes intact or ruptured; and, if the latter, how long ruptured?
8. Had vaginal examinations or attempts at delivery been made?
9. Was there any evidence of infection at the time of section?
10. What was the blood picture? If signs of anemia, acute or chronic, obtained, were grouped and cross-matched donors at hand and used if indicated?
11. If the indication was eclampsia, why was cesarean section chosen in preference to conservative treatment?
12. If the indication was placenta previa, what measures had been taken to differentiate between the complete and incomplete variations and were grouped and cross-matched donors at hand and used as indicated? Was shock combated before operation?
13. If the indication was accidental hemorrhage, what decided the choice and were donors likewise prepared and used if indicated?
14. What operative technic was used and why?
15. Was the child at term, premature, or post-mature?
16. What anesthetic was used and why?

Such reviews and analyses, in conjunction with our mortality reports, would soon tell us the character of work that is being done in our hospitals, and, in addition, would indicate more rapidly and convincingly the errors to be avoided—whether they be errors of well-meaning conservatism or well-meaning radicalism. Discussion would quickly bring out abuses and general staff influence would tend to eliminate them more effectively than would set regulations.

The meeting adjourned.

A. G. Schulze, M.D., *Secretary*

SPLINTER INJURIES CAUSE LARGE LOSS

The Department of Labor has republished and put into national circulation a report of the Bureau of Industrial Hygiene of the New York Department of Labor, which gives astonishing figures on splinters as a menace in industry. They show that in the year 1929 New York employers paid out $350,000 in compensation on account of splinters. The cost to the nation was much greater.

It would be exceedingly rare to find a workman who has not experienced a splinter injury, the bulletin points out. Such accidents run from the most trivial to the most serious, ending in death. A sufficient number of cases have been investigated to disclose salient causes, sources, remedies and preventive means concerning splinter injuries.

The average person considers a splinter injury as of minor importance and in many cases it is, but there is no certainty that it will not result in the loss of a hand or arm and it may even cause death. A splinter makes a punctured wound which the layman cannot properly treat with antiseptics. The result is a tendency to infection. This is proved by the fact that 13 per cent of compensated injuries from all causes become infected, whereas 82 per cent of compensated injuries from splinters are infected.

Under the New York State Bureau of Compensation the New York city district includes the Bronx, Kings, Nassau, New York, Queens, Richmond, Rockland, Suffolk and Westchester counties. Every day about 35 splinter injuries are reported from this district. No less than 44 per cent of these involve infection and 36 per cent of them show loss of time.

MINNEAPOLIS SURGICAL SOCIETY

Stated Meeting, Thursday, December 1, 1938

Dr. George R. Dunn, President, in the Chair

DELAYED UNION OF FRACTURES

Robert Schwyzer, M.D.
Bulach, Switzerland

(Read by Dr. O. W. Yoerg)

A most annoying situation arises when after several weeks of treatment a well reduced fracture does not show any tendency to consolidate and the ends of the fragments have the disastrous look of two pointed sticks of wood with no callus at all between them. Whether this delayed union is due to the use of the Kirschner wire extension or the nonpadded plaster splint of Boehler, I do not know. Surely the endemic goiter, so common in Switzerland, plays its part in the etiology, but does not explain all the cases of nonunion. Out of some sixty fractures I have treated within the last three years, it happened twice in transverse fractures where there was no or very little comminution and only scant hemorrhage.

The first case concerned a healthy farmer of thirty-six years who had gotten underneath his haywagon when the cows had gotten loose. He suffered a transverse fracture about the middle of the right femur with little hemorrhage and no splintering at all. The leg was put up in a Kirschner extension. This was replaced by adhesive tape at the end of six weeks. By the tenth week there was still no union and I drilled several holes about the fracture, with no result at all. At the end of the sixteenth week there existed a definite nonunion; there was very little callus and the ends of the fragments showed all the signs that promised a true pseudarthrosis.

The other case was the one of a soldier, twenty-three years of age. While riding a motorcycle he was hit by another one coming from behind. The left femur, as well as both bones of the left leg were broken. When he first came under my treatment he had been under the care of another surgeon for eight months with the result that the femur had healed well. But there was present a pseudarthrosis of the tibia, while the fibula was consolidated. He had been treated by the Kirschner wire extension also. Later on a walking plaster-of-Paris had been put on the leg. I first tried to improve the condition by drilling holes in the bones about the fracture, but had no results at all. No doubt, the advance in the healing of the fibula may, in similar cases, prevent the consolidation of the tibia.

In both these cases I performed an operation that is outstanding for its simplicity, its gratifying results, and last but not least because it was first recommended by a well known Swiss surgeon, Prof. Matti, of Berne, the successor of Prof. DeQuervain in the chair of surgery. Matti has shown that new bone will quickly form within the periosteal sac when filled with chips of cancellous bone. The ossifying power of the transplant may be due to some hormones or enzymes (phosphatase). The transplant, at any rate, remains alive and stimulates the regeneration of the bone at the ends of the ununited fragments. The most important part of the transplant consists of spongiosa. The latter acts as a scaffold for the newly forming capillaries, permitting a rich blood supply full of bone-stimulating substances. Besides, it keeps open the medullary cavities of the fragments, a principle well known through the arthrodesis of the vertebral column.

The technic is simple. An incision is made over the site of the fracture down to the bone. The periosteum is split and retracted together with the other tissues. The marrow cavities of both fragments are exposed by cutting away slices of bone with a large chisel for about 5 cm. on both sides of the fractures. The disc of connective tissue between the ends is resected down to the posterior wall of cortical bone, leaving a bridge there to act as a hinge between the fragments. There exists now a sort of a trough in the bone. An incision over the great trochanter exposes the bone. This is opened by means of a chisel or a large drill and a certain amount of spongiosa scooped out by means of a sharp scoop. This spongiosa, together with the chips resulting from the formation of the trough, are packed well within the cavities of the fragments and over the pseudarthrosis. It is important to get the transplant well packed in the cavity in order to avoid secondary hemorrhage. The periosteum is now sutured over the bone chips. Usually no attempt is made to realign the fracture, though I have done it in a third case now under treatment. I suture the muscles loosely and do not use a drain, although this is recommended by the author. The skin is sutured loosely to allow for drainage. A plaster cast is applied at the end of a week to avoid pressure.

The result in both cases was excellent. At the end of six weeks the patients were allowed to walk without splints. The farmer was back at his work within ten weeks, and the soldier was doing service again as machine gunner after six months.

OPERATIVE CORRECTION OF RECURRENT DISLOCATION OF THE HEAD OF THE HUMERUS

Robert Schwyzer, M.D.
Bulach, Switzerland

(Read by Dr. O. W. Yoerg)

It takes no little courage to present a "new" technic for the repair of recurrent dislocation at the shoulder joint. Quite a number of different procedures are known, but apparently none of them gives entire satisfaction as to operative hazards as well as lasting results. However, there are two reasons for excusing me in calling your attention to the following procedure: first, it is not new as it has given its author uniformly good results in about ten cases—some as far back as ten years. Secondly, the operation is technically simple and free of possible hazards.

Although its victims acquire a great ability to bring the head back in its proper place by some twist of the arm, recurrent dislocation of the humerus hampers its bearers a great deal in their professional activities, as well as in sports.

Two different causes are responsible for the occurrence of recurrent dislocation. One, rarely met with, is based on an anatomical abnormality, an exaggerated slanting of the glenoid cavity towards the front and the midline, combined with a weakening of ligaments and muscles. This condition is usually bilateral, calling for operation on both sides, which has been done successfully. The other cause is the previous traumatic dislocation of the head anteriorly, the subclavicular or subcoracoid luxation. In this injury the anterior part of the capsule is always ruptured, either underneath the subscapular muscle or between this one and the teres minor. The tear of the capsule is situated at the lower and anterior portion of the joint, embracing as much as half of its circumference. Laceration of the subscapular muscle and tearing of ligaments about the joint are common. Quite frequent are fractures about the rim of the glenoid cavity or a tearing loose of the periosteum of the neck of the scapula as far back as to the subscapular bursa. Even after complete reduction of the head the healing of these traumatized, hemorrhagic structures takes place in form of a more or less extended scar. The latter, being connective tissue, in time becomes stretched, the articular space widens until it lacks an appropriate support for the head of the humerus. Now even slightly forced movements, especially overextension of the abducted arm, will bring the head out of its place and cause a recurrency of the dislocation. But contrary to the first real dislocation, where the head leaves the torn capsule and buries itself within the torn subscapular muscle, in the recurrent luxations the head of the humerus always remains within the capsule.

Conservative measures usually are of no avail. Para-articular injections of blood, as recommended of late, are not very promising either. There remains the operative treatment as the one of choice. The aim of the many technics described is to restore a proper support for the head, but the ways to reach this goal differ quite widely. Some of the authors fold or excise part of the capsule (Thomas) in order to lessen the intracapsular space or combine this with a shortening or anterior transfixation of the subscapular tendon (DeQuervain, Matti). Others fasten the head in its place by a ribbon of fascia lata (Henderson) or by using the tendon of the long biceps (Kirschner, Loeffler, Rey, Rupp) or by forming a sling out of the deltoid muscle. Though the immediate results of these technics have been good, late recurrences number quite high. The transplants lacking in good circulation degenerate and stretch, and besides, these procedures are complicated and pregnant with operative hazards. A third group of surgeons follows another line of thought. They aim to build up the anterior rim of the glenoid cavity by bony or periosteal grafts. Oudard splits the coracoid process longitudinally and fastens part of it onto the anterior aspect of the capsule. Eden uses a free graft of the tibia for the same purpose. Experience proves the latter two methods as the best ones. Eden opens the joint cavity always for inspection and removal of possible loose bodies. Brun, who has somewhat modified the latter's technic, does not as a rule do this. Not incising the capsule of course greatly simplifies the operation and removes one great hazard: possible severe infection or trauma to the joint surfaces with subsequent partial or total ankylosis. Brun has done ten cases with very gratifying results. They have been published in the *Schweizerische Medicinische Wochenschrift*, 35:844, 1936.

The principal points of his technic are: General anesthesia, strictest asepsis, upper arm in slight abduction, elbow at a right angle, forearm in supination. Incision is made along the anterior margin of the deltoid muscle, from the clavicle down to the point where the pectoral meets the deltoid. Flat hooks pull the pectoral together with the cephalic vein mesially, the deltoid laterally. The landmark of the coracoid process is searched for and the short head of the biceps dissected, pulling it mesially. Now the capsule lies free and relaxed within the back of the wound, as well as the subscapular muscle. It is not necessary to incise the latter. One can easily pull it downwards when rotating the arm inwardly. The palpating finger easily finds the margin of the glenoid cavity with its bony rim. Only exceptionally does the narrow incision allow one to do the next step under control of the eye. But this is not necessary.

The fingertip resting on the rim of the glenoid cavity, the periosteum is incised parallel to the rim for about 3 cm. and 1 cm. behind it. Using the raspatory, one looses the periosteum in the form of a pocket down to the bases of the neck of the scapula. The chisel cuts loose a small plate of bone, leaving it in connection at its base with the scapula, thus forming a cleft to receive the graft. This insures a solid healing on of the graft. The wound is now packed with gauze. In the usual technic a graft is taken from the tibia having the full breath of the latter and a length of about 7 cm., the graft to be about 4 millimeters thick, thinning out on the one end, and has to carry periosteum on the one side, bone trabeculæ on the other. On the thin end a little hole is drilled. The graft is then placed inside of the pocket on the scapula by means of a few blows with a hammer. It is to lie close to the joint capsule and to lean against the coracoid process, to which it is fastened by a silk suture through the aforementioned hole in its thinner end. A few stitches of silk are taken through the short head of the biceps and the joint capsule, thus burying the graft and fixing it still more in its new bed. A few sutures reunite the superficial fascia. No drainage is used. The skin is closed by silk or metal sutures. A plaster-of-Paris splint holds the arm in slight abduction. The sutures are removed on the tenth day, the plaster remains for about 5 weeks. The incision on the leg is taken care of the usual way, taking care to put the leg into a plaster splint for fear of possible fracture.

According to this technic I have treated two cases. The first one concerned a young girl with bilateral loose joints, but recurrent dislocation only of the right one. She was unable to do her housework or board a street car without having a recurrence at the slightest overextension. It is now more than two years since the operation and she has never had a recurrence, doing all her work. The convalescence was entirely smooth, the scar is hardly visible and the leg in fine condition.

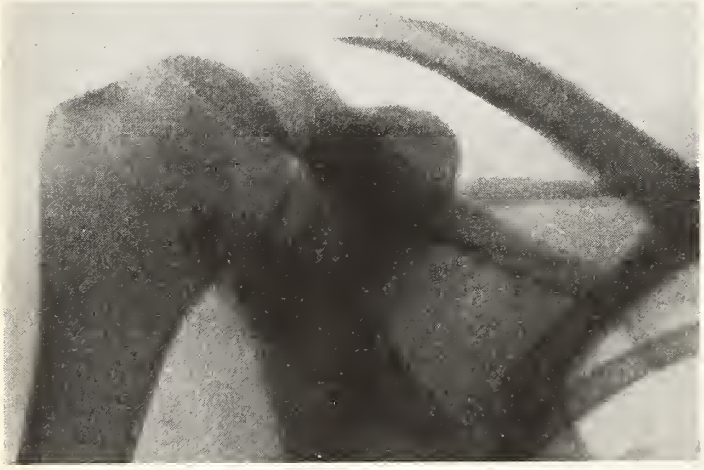

Fig. 1. Radiograph of shoulder made five months after operation shows bone transplant which has become somewhat displaced.

The other patient, a factory worker for twenty-three years, underwent a traumatic dislocation two years ago while engaged in a wrestling contest. The luxation was set and healed well but only to recur about every time he reached up to fetch something from a shelf. He is a very muscular type of a man and I had some difficulty to fit the graft into its proper place. He made a good recovery, being back at the factory within six weeks. He has not had a recurrence since the operation one and one-half years ago, although wrestling and doing military service as a machine gunner again.

Discussion

Dr. Vernon Hart (by invitation): I have had no experience with the anterior bone graft operation for recurrent dislocation of the head of the humerus. The method that I have been using is the physiological block, utilizing the long tendon of the biceps muscles which has its normal attachment of origin to the anterior and superior rim of the glenoid cavity. I am sure you are familiar with the operation.

There are two methods: (1) In the Nicola operation the biceps tendon is severed and introduced through a tunnel drilled through the head of the humerus and then resutured. (2) In the Roberts operation, the tendon is buried in the deepened bicipital groove of the humerus. In both operations the biceps tendon becomes fixed to the shaft just distal to the head of the humerus. The second method is much simpler and avoids many of the technical difficulties of the first.

I have seen several patients in other Clinics who have been treated by the anterior bone block method and the results were very satisfactory.

I would also like to say a few words relative to the first paper regarding the use of multiple cancellous bone chips instead of a massive compact bone graft for treatment of non-union fractures. The procedure is a very logical one because the amount of new bone that is stimulated from a bone graft depends on its surface area in contact with the surrounding tissues. If a massive bone graft is broken up into a multiplicity of small chips there is much more chance of revascularization with more egenerous callus formation resulting in solid union of the non-union fracture. The principle upon which the operation depends is that instead of a massive graft there is an abundance of small bone chips with a larger surface area in contact with vascular tissues. Revascularization is much more complete when using cancellous bone since there is a more abundant supply of osteogenetic cells and vascular cells. When using tissue for multiple bone chips, spongy or cancellous bone, I would suggest using the crest of the ilium where a great quantity of the bone may be obtained. I have enjoyed and greatly appreciated the two papers prepared by Dr. Schwyzer.

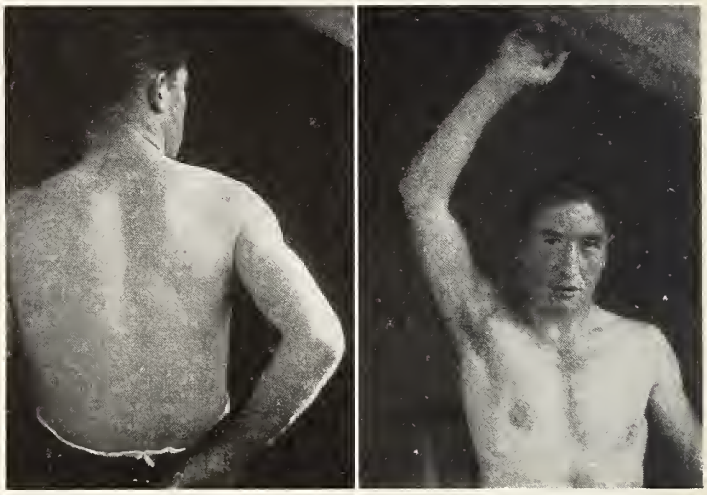

Fig. 2. Pictures of patient eleven months after operation.

A Letter from the Author

28th of September, 1938

Dear Doctor:

While there is big talk about war or peace again in old unsettled Europe I beg you to take the enclosed little papers of a country surgeon as a token that Switzerland is still quietly trodding along in the hope it may be spared the rigors of war. With greatest pleasure and hope, we all have read the message of your president to the world, still admiring the good common sense of the true American statesman. Our hope is that reason may rule over fanatisme.

The Surgical Society of Minneapolis has treated me so friendly and gentlemanly while I was still amongst you and ever since, that I felt it for a long time my duty to contribute something, ever so unimportant, for your meetings. Here it is. I dare to hope you may show or read it to the members and they may enjoy it. My English, of course, has suffered a great deal since I am forced to talk my country slang all day long. I beg you to pardon me for it.

A couple of weeks ago I had the pleasure of showing "my" hospital to Dr. Arnold Schwyzer who brought me long desired first hand news of Minnesota. Is it vain to wish to see one of you at my home at his next visit to Europe?

Many kind regards and good wishes to you and all others who ask about me. If you can't use the papers, throw them away.

Yours sincerely,

Robert Schwyzer, M.D.

THE INJECTION TREATMENT OF HYDROCELE

Arthur F. Bratrud, M.D. and Carl Eckhardt, M.D.
Minneapolis

Injection treatment of hydrocele has not been extensively used, but it is becoming more popular as the laity is becoming educated to the fact that they can be afforded relief by an office procedure which is not difficult, and without serious complications. In spite of modern improvements in surgical technic, patients are still reluctant in submitting themselves to surgery. Industry demands that patients be treated and returned to work in minimal time, consistent with safety.

The injection treatment of hydrocele has had its eras of popularity as well as those of disrepute. Treatment of hydrocele by the injection method can be traced to the Romans, at which time, Celsus injected salt peter into the tunica vaginalis. The procedure gained favor again during the seventeenth century, after a long period in which there was very little interest manifested in the method. Lembert treated cases by injecting sublimate which was dissolved in lime water. Two Scottish Army surgeons named Murro reported a number of cures using hot and cold water or red wine. In 1832, Sir Randall Martin of Calcutta discovered the use of tincture of iodine, where at a single hospital, 2393 cases were injected with iodine over a period of seven years and successful results reported in 99 per cent. Interest was manifested in this form of treatment by Kocher, Bull, McBurney, Billroth and Velpeau and they reported favorable results from the injection treatment. Huter of Germany is credited with first having used phenol, and in 1881 Levis of America popularized the treatment of hydrocele by the injection of this solution. He maintained that there was less pain, less sloughing, only two days away from work, and that more cures resulted. In 1903, Luke of Georgia used iodine and phenol and stated that results were very uncertain, resulting in considerable pain and swelling, and as a result the procedure fell into disrepute. Morestin of Paris, in 1912, treated cases by injection of equal parts of phenol, glycerin, and alcohol (Morestin's solution) after withdrawing one third of the fluid within the hydrocele. After treating a number of cases he modified his technic by withdrawing more fluid from the hydrocele sac and reinjecting more of the solution, and treating only simple hydroceles.

In 1912, Mellanah described a vaccine which he injected into the sac. This was discarded on account of the inflammatory reaction which followed, although the results were reported as good. In 1912, Bruns of Germany reported 1593 cases treated with phenol, having a recurrence of 6.1 per cent. In 1915, Soubeyron injected one gram of 40 per cent alcohol diluted with equal parts of water, without aspiration of any of the fluid. Zinc sulphate was later used by Dimmucher and Palaillon, but recurrences following this solution were high, and as a result it was abandoned. In 1922, Hoffman used one sixth cubic centimeter of alcohol and phenol, treating only simple hydroceles, not larger than an orange. Pain resulted from this solution, and if too large a quantity was used, or if any of the solution filtrated through the tunica vaginalis, cellulitis and suppuration occurred. Veazy, in 1925, introduced a sterile catheter into the collapsed sac. Prior to this a coil of sterile catgut had been used.

The treatment of varicose veins by injection of sclerosing solutions marked the greatest advancement in the safe treatment of hydrocele by injection. In 1930, Pybus reported five cases treated with quinine hydrochloride and urethane with excellent results. In 1931, Parritt and Levi treated thirty cases with sodium morrhuate, stating that cures resulted in all cases. Sharma in 1929 used a mixture of quinine dihydrochloride with 0.5 per cent salicylic acid, but results were not reported.

An excellent scientific study of solutions having merit for hydrocele injection was reported by Murray and Kilbourne in 1932. Their objective was to find a solution which would meet the following requirements: lack of pain, no disability, efficient to destroy all hydroceles without recurrence, non-toxic, bactericidal, and without danger of hemorrhage into the sac following injection. As a result of their work the solution of choice was quinine dihydrochloride 13.33 per cent and urethane 6.66 per cent. Of all preparations used it gave the best results with the least reaction. Most of the solutions previously used resulted in severe excruciating pain. Phenol produced severe pain when injected in strong solution or pure and it was believed that it produced a local cauterization and slower absorption. It was believed that phenol was more toxic when injected into the hydrocele sac than when injected into the abdominal cavity, for the liver detoxifies it, while in a hydrocele sac the liver becomes short circuited. Three cases of nephroses were reported by Murphy after injection of phenol in the treatment of hydrocele. L. W. Riba in 1933, reported the only case to be found in the literature of scrotal gangrene following injection of phenol for hydrocele. Quinine may produce complications, as cases of optic nerve atrophy have been reported following oral administration of quinine. From experimental work on rabbits by Kilbourne, injection of solutions into the pleural cavity revealed phenol to be five times as toxic as quinine. In 1935, Livermore introduced the technic bearing his name. After aspiration of the hydrocele with a large gallbladder trocar, the sac was packed with narrow shoe string tape saturated with five per cent sodium morrhuate. This tape was not disturbed for a period of twenty-four hours and then was gradually removed from day to day, being removed completely at the end of one week. From this procedure he reported sixteen cases with one recurrence. Kietzer in 1936, suggested the treatment of recurrent hydrocele by x-ray therapy. However, this method must be reserved for old men because of the danger of complete sterilization. Biederman in 1938 reported six cases treated with sylnasol, and all were cured.

Incidence.—Greene reported that 2 to 4 per cent of all urological admissions have hydroceles. Some say as high as 10 per cent. Fifty per cent occur after the age of forty years. The condition is bilateral in four per cent of the cases. Campbell and Caforio reported the largest hydrocele on record. This hydrocele contained five gallons. The incidence is highest among those people whose work subjects them to scrotal trauma, such as cowboys, circus riders, et cetera.

Character of Fluid from Tunica Vaginalis.—As reported by Greene, fluid from a simple hydrocele looks like urine, is slightly sticky, and tends to foam if the vessel is agitated. It is markedly alkaline, specific gravity 1.020-1.026, contains 4 to 6 per cent albumin, some fibrinogen, fibrin, salts, sometimes cholesterin, traces of glucose and occasional fibrin bodies and lime salts. Microscopically, a few endothelial cells, leukocytes, cholesterin crystals and lecithin bodies are found. Spermatozoa may be present if a ruptured spermatocele communicates with the sac. Red cells are found only in case of hemorrhage and bacteria only in infected cases.

Fluid from a spermatocele is hazy, opalescent and mildly alkaline. Specific gravity ranges from 1.002-1.006, there being only a small trace of albumin present. Microscopically, many dead sperm are present, but if there is an opening into a seminiferous tubule, many active spermatozoa are seen.

A hematocele contains blood and is always due to trauma.

A chylocele, which is rare in the temperate zone, is often seen in the tropics. It is caused from filarial infection. The aspirated fluid in these cases is milky and, when allowed to stand, a layer of fat accumulates on its surface.

Theory and Etiology of Cure by Injection.—The entire endothelium of the hydrocele sac could be damaged to cause an out-pouring of fibrin ferment. In theory this fluid should clot and cause obliteration of the sac. The supposition is that by introducing some fluid into the sac an irritation is produced, causing an inflammatory reaction within the serous lining, whereby the opposing surfaces adhere. Since endothelium is of mesodermal origin the repair process following this reaction leads to the production of fibroblasts and ultimately occludes the sac by fibrous tissue.

Huggins and Entz studied problems of absorption from the tunica vaginalis, testis, hydrocele, and spermatocele, and found there is a constant interchange of fluid within all serous lined cavities and any accumulation of fluid must be due to an imbalance of either secretion or absorption. They found marked delay in the absorption of dye from a hydrocele as compared with normal tissue of the tunica vaginalis.

Ewell operated upon one of their cured patients one month after the last of three injections of quinine and urethane. He found a small amount of dark, amber fluid, and several long strands of loosely attached and organized fibrin. Grossly, the testis and epididymis appeared normal. Microscopic section of the tunic wall showed the endothelium to be intact, the blood vessels appeared normal, and the subserous layer of tissue distinctly thickened and infiltrated with organized fibrous tissue.

They assume from this case that the resulting fibrosis of the tunic wall after injection interferes with the blood and lymph supply of the endothelium, and that this in some way changes the process of fluid formation.

Differential Diagnosis.—Hydroceles ordinarily are not difficult to diagnose, although at times some difficulty may be encountered. Where a complicating hernia is present it may be differentiated by transillumination of light through the sac, although this may not be present if incarcerated omentum is present in the scrotum. A spermatocele can be only differentiated from a hydrocele by microscopic examination of the fluid content, although very rarely will a spermatocele be seen that obtains any great size. In a chronic hydrocele which has been aspirated a number of times without having been given treatment, the sac may be extremely thick, and it may not transilluminate light very clearly. Any neoplasm, benign or malignant, can be determined by palpation, although, if complicated by a hydrocele, transillumination will not be so clearly shown. Aspiration of the contents, as a rule, shows a blood-tinged fluid to be present. Hematoma should not be difficult to differentiate as it usually follows injury and will reveal bloody fluid. A gumma of the testicle may or may not result in positive Wassermann of the blood, but examination of the spinal fluid should aid in the differentiation. The mass will not be transilluminated. Tuberculosis of the epididymis may or may not have associated hydrocele present. The nodular or indurated area of the epididymis would be indicative of pathology and this would contraindicate treatment.

The first cases which we treated were injected with glucose fifty per cent, in 1928. The results were good, but there was marked pain associated with treatment and following treatment, as well as marked edema. A few cases were treated with sodium morrhuate, but edema of the scrotum was marked and there was marked pain after treatment. When sodium morrhuate was used the reaction was of a more serious character, resulting in a thickened, indurated scrotum, and it seemed as though the entire side of the scrotum was one adherent mass. Since 1932, solutions of quinine urethane mixture recommended by Kilbourne (quinine hydrochloride 13.33 per cent and urethane 6.66 per cent have been used, and have been found to be very efficient with less reaction and better results. The ideal solution is one that is not painful, does not cause incapacitation, is non-toxic, bactericidal, and is efficient in the cure of hydrocele. Quinine hydrochloride with urethane comes closest to this of any solution used.

Indications.—The indications for treatment are confined to simple, chronic, non-infected types of hydrocele, and includes hydrocele of the cord. Hydroceles complicating a hernia where the sac is separated from the hernia can be treated. Wherever a hydrocele is complicated by epididymitis, tuberculosis, neoplasm, or syphilis, injection therapy is contraindicated. Nor should a case of abdomino-scrotal type of hydrocele be treated, as this is always associated with hernia and there would be danger of injecting the fluid into the abdominal cavity. Where there is calcium or cholesterol degeneration present in the sac, surgery is indicated. Hydrocele associated with undescended testicle is a surgical condition. Should the aspirated fluid be blood-tinged, then the case is surgical.

Technic.—The scrotum should be prepared the same as for any surgical procedure.

1. The scrotum should be shaved, washed with soap and water, and painted with any good antiseptic, mercresin, merthiolate, et cetera.
2. A bloodless area should be selected on the lower part of the scrotum, at which point a wheal should be made, using two per cent novocain without adrenalin.
3. After the bloodless area on the scrotum has been anesthetized, with an eighteen gauge needle attached to a twenty cubic centimeter syringe the fluid is aspirated as completely as possible. It is advisable to have an assistant hold the scrotum during this period of aspiration so as to lessen the danger of the needle becoming displaced during the procedure. After aspiration, the testicle and epididymis should be palpated to determine whether there is any evidence of tuberculosis, epididymitis, gumma or neoplasm. After complete aspiration has been made, and being satisfied that the needle is still in the tunica vaginalis, quinine hydrochloride and urethane mixture is injected into the sac, using not over two cubic centimeters at the first treatment. Should subsequent treatments be necessary, the quantity can be increased up to as high as ten cubic centimeters, although in our cases we have not used over four cubic centimeters. After the needle has been removed, the scrotum should be gently massaged so that the fluid will contact all parts of the sac. Sterile dressing should be applied over the sac after application of collodion. The patient should be told that fluid will recur immediately and will probably be as great or greater on the day following treatment, than it was at the time of treatment, but that he can continue his work as it will only be a question of time until swelling and edema of the tissues begin to disappear and absorption of the hydrocele fluid begins. No attempt should be made to re-treat the case or aspirate for at least six weeks. A firm fitting suspensory or athletic support should be worn after treatment.

Causes of Failure.—Causes of failure, in order of their importance, are:

1. Incomplete aspiration of contents of the hydrocele.
2. The use of too little fluid.
3. Too strong a solution.
4. Complicating conditions such as epididymitis or injury to the epididymis or testicle during procedure.
5. Production of a hematoma as the result of puncture of a blood vessel during aspiration.
6. Multilocular hydrocele.

Course After Treatment.—Occasionally, patients will have no pain or edema of the scrotum or scrotal tissue after the treatment, but the majority will have both. The pain will vary with the type of solution used, being nearly painless with the quinine mixture. With sodium morrhuate there is danger of allergy, and, on account of the condition of the scrotum after treatment, this was discontinued. There is edema of the scrotal tissues with recurrence of the hydrocele the day after treatment, but this will begin to absorb up to ten days, although it may require a period up to six weeks. These cases should be left without further treatment until absorption begins. When quinine hydrochloride is used there may be pain present, although in the majority of cases it is not of any serious character. When repeated aspirations are made the fluid will be found to be cloudy and contain fibrous shreds.

Complications.—When strict technic is carried out, the danger of infection is very small. When an avascular area is selected for the insertion of the needle there is little danger of hematoma. If no chronic infection is present there should be very little danger of epididymitis or orchitis. In other words, with properly selected cases complications should be rare.

Results of Treatment.—Of the cases which were treated with glucose solution, we were unable to obtain records, although results were good as far as they reported for observation. Since records were kept of any cases, seventy-two patients have been treated. Of this series, one was referred to surgery after receiving six injections, as there was a complicating hernia. Three patients were referred to surgery as the fluid was blood-tinged and neoplasms were suspected. At operation, diagnosis of neoplasm was confirmed. Cures have resulted in all cases, although some of the patients have required a large number of treatments. One received a series of twenty injections, although, if this patient were to be treated now, he would not be given as many treatments, but given more time so as to determine if complete absorption would not have taken place. This man had, however, a bilateral hernia which had been operated upon eight times, two of them being plastic repairs. Not a single patient has suffered enough pain and swelling so as to be disabled. When pain does occur it usually is present immediately after injection of the quinine urethane mixture, but it usually goes away in the course of one or two days. Two of the patients who were treated have had recurrence following surgery. One patient developed a hematoma, but cure resulted after aspiration of the bloody fluid. A man sixty-nine years of age, who was being given treatments for a scrotal hernia at the hospital, had severe pain associated with marked swelling and redness of the scrotum after treatment of a hydrocele on the opposite side, that contained over four hundred cubic centimeters of fluid. Purulent material was found on aspiration, although this was not confirmed by microscopic examination or culture. This patient has a cure with no more treatments or aspiration.

HYDROCELES

Age Group	1 to 10	10 to 20	20 to 30	30 to 40	40 to 50	50 to 60	60 to 70	70 to 80
No. of Cases	4	4	6	6	6	10	23	13

NUMBER OF TREATMENTS

	1	2	4	4	5	6	7	8	9	10	14	20
No Cases	35	11	5	4	1	1	11	0	0	2	1	1

Of the patients treated, three were referred for operation as the aspirated fluid contained blood. These all proved to have neoplasms. One was referred for operation after seven unsuccessful treatments. Two of those treated had previously been operated upon and had recurrence of the hydrocele. Both resulted in cures. One patient had purulent material on second aspiration, but this cleared up without drainage or other complication.

Conclusions.—In conclusion it may be stated that injection treatment of hydrocele with sclerosing solution is a practical procedure with simple technic, with definite advantage over surgical treatment, in the cases where there is no contraindication. It results in a very high percentage of cures if confined to chronic, non-infected types without associated disease such as neoplasm, tuberculosis, or syphilis, or in cases of abdomino-scrotal types of hydrocele.

Discussion

Dr. H. O. McPheeters: In these days of WPA, XYZ, et cetera, it seems that the only reputation a man need have for a job is to be on the inside, put up a good front and bluff. Just now, I feel a good deal that way, and I realize how incompetent I am to discuss this paper. However, I feel that only a few men have treated many of these cases, so I am happy for this chance to add my report.

Dr. Bratrud is to be congratulated on having the opportunity to see more than the occasional hydrocele, let alone presenting a series of 72 treated cases. It is the largest series as yet presented by any recognized authority.

This is just another one of the truly surgical procedures that is being taken out of the hands of the quack and placed on a sound, rational basis. As Dr. Bratrud said, Kilbourne and Murray's paper is by far the best paper that has been presented on the subject. They have gone into it most thoroughly and in detail from all angles and have covered it the best. They take up the differential diagnosis and this I believe is a very important point even though more theoretical than real; but it must be stated at the outset. They also take up the contraindications and emphasize that the abdominal-scrotal hydrocele is the one that should not be injected.

The hydrocele sac is, in a sense, a peritoneum-lined pouch. There is no reason why the peritoneum should not respond to irritants here the same as elsewhere. We all know the care we must take to avoid adhesions following abdominal surgery and how at times the surfaces adhere firmly together in spite of our efforts. This being the case, it is certainly logical that we should expect good results following the presence of known irritants. In my cases the reaction has been so severe that I feel sure the sac has been obliterated, even though, as Dr. Bratrud reports, some cases clinically cured, show the serous pouch still present. To me this is the one weak spot in all this work. More microscopic studies must be made of the hydrocele sac of treated cases.

I was surprised at being unable to find any good report on the tissue change developing in the sac following the injection of the sclerosing fluid. There is only the report of an occasional case that happened to come to surgery where there has been any study made of the hydrocele sac following the injections.

I have only cared for eight cases myself, two of these were bilateral; the youngest patient was sixteen years and the oldest sixty-four. I have used sylnasol, sodium linsoleate and sodium morrhuate. I have had good clinical results in all cases, with no untoward results. At the time it pained the patients severely and they complained of much soreness locally for several days as a rule. To me this is a severe criticism of it. One patient was in moderate shock for one hour due to the severe pain. This was following the use of sodium morrhuate.. This patient, however, got the quickest end-result of any and now, two months post-injection, the testicle is but little larger than the other one. In this case the hydrocele was about the size of the average hen egg and held about 20 c.c. of fluid. Two patients had the second injection.

I have seen one case of gangrene of the testicle following injection. (It was not mine.) I saw it when it was operated upon by another surgeon. The solution injected was not known and we could not find out. The patient did not know.

In all these reports, Bratrud, Kilbourne and Murray, et al, they say quinine and urethane is now the accepted solution. I cannot understand why we can inject 2 c.c. or even 4 c.c., or 5 c.c., or, as one writer says, 10 c.c. of quinine urethane solution into the hydrocele sac and not expect a slough. If you get 0.25 c.c. or less of quinine and urethane perivascular in a varicose vein injection you will almost invariably have a slough develop. I have seen so many sloughs myself and have had so many, I frankly admit it, that I absolutely will not use quinine and urethane in any way in varicose vein injections. How we can turn around and inject 2 c.c. to 10 c.c in a hydrocele sac which is closed and get away without any slough is not easily explained. It doesn't seem reasonable but all the authorities, including Kilbourne and Murray, in their large series, with Dr. Bratrud has stated previously in his papers on do it, so we have to accept it. Until the pathological reports give further proof, we will have to take it as it is.

One very important thing Dr. Bratrud spoke of but didn't emphasize enough, it seems to me, is the size of the testicle before your injection, thinking entirely of a medico-legal situation. You will oftentimes find, as Dr. Bratrud has stated previously in his papers on the "The Injection Treatment of Hernia," that you have an atrophy of the testicle when the patient first comes to you. One testicle may be much smaller than the other, and following the operation it makes a beautiful opportunity for a medico-legal situation, a malpractice and damage suit, to be developed.

One of the points in regard to technic that I do not think Dr. Bratrud brought out, and yet that I believe is important, is the introduction of the needle. I like to grasp the scrotum with my left hand, being right handed, and have the syringe and needle in my right hand. Always have the scrotum and hydrocele in firm grasp of your hand so that the skin above, as Dr. Bratrud suggested, is very tense. Second, introduce the needle and not only introduce it just through the skin and the sac lining, but well down inside at least an inch so that the needle is well inside the cavity. In my own cases, until I did that, I found that the needle would easily slip back and outside of the sac.

One of the things one man suggested, a very clever suggestion, was to have a two-way stop-cock between his syringe and his needle and then using a luer-lok syringe with rings for fingers and thumb he could aspirate the fluid while the assistant could turn the two-way stop-cock so he could discharge it and aspirate again and empty the hydrocele. I simply have the nurse unlock the syringe while I continue to hold scrotum, hydrocele and needle in the left hand and the syringe in the right. That works just as well.

I think it is very important to have the patient fitted, as Dr. Bratrud suggested, with a very tightly fitting all elastic jock strap and have it *in place* before you start your injection. Until I did that I had trouble. If you tell the patient to go home and get a jock strap and put it on and wear it afterward, he will not do it with the same care, caution and support that you want and I think it is very important, not only to have a tight fitting jock strap, but then to pad it up yourself with gauze and sheet wadding until you know that it is padded with extreme pressure. The more pressure you can have immediately after the injection, the less pain the patient is going to have during the next two or three days and the less possibility there is going to be of fluid recurring.

A great many complications will develop following this treatment just as there did in the early days of the injection treatment of varicose veins. If the operator is careful, uses common sense and good judgment, there should be no serious trouble.

THE ONE-STAGE ABDOMINO-PERINEAL PROCEDURE FOR RECTAL CARCINOMA*

Walter A. Fansler, M.D., F.A.C.S.
Minneapolis

This particular operation is presented, not because it is something new, but rather because it is a procedure which has been definitely accepted as having an important place in the operative treatment of rectal carcinoma. In the past, the only objection has been the high mortality rate. With the improved methods of preoperative preparation, postoperative care and better operative technic, this mortality rate has been substantially reduced. In a large series of cases it has been shown that, with experience, the operation can be performed with a low operative mortality, and it does possess certain definite advantages over other operative procedures. Miles, of London, who originated the operation, has reported several hundred cases. More recently, Jones, of the Cleveland Clinic, reports a series of three hundred cases with a mortality rate of 9.8 per cent. Rankin has operated upon seventy-five patients with a mortality rate of 6.6 per cent. From this report one would assume that Rankin accepts only the more desirable cases for this method of operation. In general, this method should be reserved for those patients who are in fairly satisfactory physical condition, and in whom the lesion is suitable for radical removal. For those patients in poor physical condition, less radical operations may be to their advantage. Our only contention is that in patients who are thought suitable for a radical abdomino-perineal removal of their growth the operation is best done in one stage rather than in two stages.

It is an accepted surgical axiom that the best operation for cancer is the one which permits the widest removal of the growth together with its gland-bearing area. In cancer of the rectum this is best accomplished by some form of abdomino-perineal operation. At least five advantages may be claimed for the one-stage operation over the multiple-stage procedure.

1. The entire operation is completed at one time. The patient does not have to submit to the danger, distress and worry incident to two laparotomies.

2. I believe the one-stage operation can be done more quickly, more easily, and with less shock than the second stage of the two-stage abdomino-perineal procedure. In opening the abdomen for the first time, the peritoneal cavity is usually clean and free of inflammation and adhesions. Under these conditions, the necessary dissection can be quickly and cleanly done. Upon opening the abdomen for the second time to complete the second stage of an abdomino-perineal resection, one almost invariably encounters adhesions and inflammation. The presence of this inflammation and the freeing of the adhesions greatly slows up the removal of the diseased bowel. In the Lahey operation, in addition to the above factors, the cut end of the distal portion of the bowel must be dissected free from the abdominal wall and inverted.

3. In doing a two-stage operation the patient is twice subjected to the inherent dangers of a laparotomy over which the surgeon has no control. Furthermore, the patient having had one laparotomy is within three to six weeks subjected to a second. The question is whether, in this length of time, any patient can make an adequate recovery from a laparotomy. I do not believe that many surgeons would advise two laparotomies in such close succession if it were possible to allow a greater length of time to elapse between them.

4. In the one-stage procedure the cancer is removed at once. In two-stage procedures the growth is left in the patient for three or four additional weeks. In case of complications, it may be two or three months. When a cancer is discovered, the patient is always advised to have it out "at once." Why is this not an important factor here? Who knows upon what day metastatic spread may occur?

5. The period of hospitalization and disability is less with the one-stage procedure. This factor, of course, is a minor one in comparison to the safety of the patient, but if safety is not sacrificed, then time should be considered.

With patients who are good physical risks there is but one condition where the two-stage procedure is better than the one stage. This is in patients who have a bowel obstruction which cannot be relieved by medical means. In such cases a preliminary surgical decompression should always be done to relieve obstruction. In the presence of obstruction, the removal of a rectal or colonic growth should never be attempted.

---

*Read by invitation.

To date, I have operated upon twenty-eight patients by the one-stage abdomino-perineal method. From this experience and the observation of other operators, I have come to certain conclusions concerning it. I am presenting this paper to discuss these points.

The preoperative preparation is important, and I shall enumerate the more essential points. Sufficient time should be allowed for preparation. At least a week is usually necessary and more time should be allowed if thought advisable.

Anemia.—Many of these patients have a certain degree of anemia. We feel that in all cases the hemoglobin should be raised to at least seventy-five per cent before operation. Repeated transfusions is the quickest and best method of accomplishing this.

Weight Loss, Dehydration, Low Sugar Reserve.—It is not possible to build up weight loss, but a high caloric, low residue diet, together with transfusions will be a great help. Increased fluid intake and intravenous glucose improve the general condition of the patient.

Bowel Preparation.—The bowel should be empty at the time of operation. If there is no obstruction, one or two doses of an ounce of epsom salts will accomplish this. In the presence of moderate obstruction, it may be necessary to give, over a period of a week or more, daily doses of mineral oil and epsom salts. Small daily saline enemas are advisable until twenty-four hours before operation.

If these measures are carried out and physical and laboratory examinations reveal no serious organic lesion, the patient is usually ready for operation.

The operation is a formidable one. Simply as a matter of mechanics, there is a great deal to be done. Unless the surgeon organizes and coördinates the steps of the operation, he may be puttering around the entire morning. Prolonged operating time greatly adds to the risk of the surgical procedure.

Anesthesia.—In most cases the average surgeon must plan upon two or more hours of anesthesia. This means the administration of two spinal anesthetics, the combination of spinal and general anesthesia, or the use of general anesthesia throughout. We have tried all combinations. Until the development of a spinal anesthetic which would give at least an hour and a half of anesthesia, we were of the opinion that in most cases ether anesthesia with gas induction was the safest and most desirable. The reason for this was that it is often impossible to complete the abdominal portion of the operation within an hour. This made it necessary to switch to inhalation anesthesia in the midst of the abdominal operation. With spinal anesthetics lasting ninety minutes or more, one can complete, in almost all cases, the abdominal portion of the operation and have a residual anesthesia carried over for the perineal section. If necessary, a small amount of gas may be given for the completion of the perineal excision. We now use both types of anesthesia, spinal plus gas, or inhalation ether anesthesia alone.

A great number of special instruments are not necessary, but the operation is much easier if one has a very long pair of scissors, several very long hemostats, and a pair of long tension forceps. They enable the surgeon to work deeply in the pelvis and to see clearly what he is doing. With ordinary instruments, it is necessary to put the hand so far down into the narrow pelvis that the operative field is obscured.

With the aid of some slides, I will now go over the steps of the operation as we perform it. [Here, seven slides were shown and discussed.]

The postoperative care is most important, since in these patients death is usually due to some complication and not to the immediate effects of the operation. Transfusions are of great value. Almost all patients are transfused at least once. If there is evidence of shock the blood is given before the patient leaves the operating room. If there is no evidence of shock the transfusion is given later in the day. If the patient does not seem to snap back quickly, the transfusions are repeated for several days.

Nasal Suction.—We feel that nasal suction is most valuable in these patients. Suction is begun in all of these patients as soon as they are returned to their rooms. Where formerly the majority showed considerable distention with discomfort and borborygmus, now almost all have flat abdomens and are comfortable. We believe there is less chance of ileus or necrosis of the colostomy stump where suction is used.

Fluids.—There is usually considerable loss of fluid at the time of operation. We compensate for this by giving the patient 1,000 c.c. of five per cent glucose in Ringer's solution. If a transfusion is given, this may be omitted. The average patient will require about 3,000 c.c. of fluid in twenty-four hours to maintain his fluid balance. This is given as 1,000 c.c. of 5 per cent glucose intravenously and 2,000 c.c. of normal saline by hypodermoclysis. If the tongue seems dry and the urinary output is less than 800 c.c. the amount of fluid is increased. The patient should have sufficient fluid, but we believe that the indiscriminate use of large amounts of fluid, especially intravenously, may do more harm than good. Hyperventilation and frequent moving of the patient seems advisable, but more especially in older patients.

The use of acidulated fruit drops and chewing gum helps to keep the patient's mouth comfortable and to prevent the occurrence of parotitis.

These patients often have difficulty in voiding. For this reason a retention catheter is usually left in male patients. This renders repeated catheterization unnecessary, and keeps the bladder contracted for several days. When the catheter is removed and the bladder becomes distended, there seems to be greater ability to void than in those cases where the bladder has not been kept contracted.

The colostomy is usually punctured after forty-eight hours. This is done with a small cautery tip, anesthesia not being necessary. If the patient passes gas freely, fluids are given by mouth with the suction apparatus closed. If the fluids are well tolerated, suction is removed. The patient is then given fluids entirely by mouth and the parenteric fluids discontinued.

As has been stated, death usually occurs as the result of complications. The most frequent serious complications are peritonitis, pneumonia, ileus, obstruction, sepsis, thrombosis, embolism, cardiac failure, and urinary infection. Our series of twenty-eight cases were divided between private patients and those operated upon at the General Hospital. There were five deaths as follows: male, aged 58, nine days postoperatively of peritonitis and pneumonia following the partial necrosis of his colostomy loop; female, aged 63, twenty-six days postoperatively of spinal meningitis due to infection by the colon bacillus; male, aged 62, five days postoperatively of broncho-pneumonia; female, aged 52, sixteen days postoperatively from infarct of the lung followed by pneumonia; male, aged 46, three days postoperatively, cause not determined, and autopsy was refused.

It is a matter of opinion as to the percentage of cases which should be operated upon by this method. It depends somewhat upon the skill and experience of the individual surgeon. In our own practice during the past three years, in those patients we have accepted for radical operation, we have done the one-stage abdomino-perineal operation in 70.4 per cent of the cases.

In conclusion, I wish to state it is our opinion that, barring obstruction which cannot be relieved by medical means, any patient who can survive a two-stage procedure abdomino-perineal operation will tolerate a one-stage procedure as well, or better. The mortality rate should be less rather than more, he has his growth out earlier, he is saved the risk, pain and anxiety of a second operation, and his period of hospitalization and disability is less. There is a group of operable cases in which, because of physical impairments, no form of abdomino-perineal operation is advisable. The best procedure in these cases is a simple colostomy, followed later by a perineal excision of the rectum. In general, we have divided our cases into three groups: those suitable only for palliative measures, namely colostomy, fulguration, et cetera, those permitting colostomy and later perineal excision of the rectum, and those suitable for the one-stage abdomino-perineal operation.

Discussion

Dr. A. A. Zierold: It should be relatively easy to discuss a paper such as this because it always should be easy to talk about your troubles; but it is a little bit difficult to add, by way of discussion, anything to what has been said. I think everyone who is operating in and about the rectosigmoid has approached it with considerable trepidation. It is formidable surgery. To my mind, it is the most difficult surgery that we have to undertake and in many ways it is surprising why it should be so. Hemorrhage is not a great factor; we are not really concerned with bleeding, we are not really concerned with difficult anastomosis; we are oftentimes simply overborne by the amount of work there is to do in the resection of the rectosigmoid.

As far as I can determine, from what I have seen and more from what I have read, there is no question as to the worth and the advisability of an abdomino-perineal operation. It is the most complete operation that can be performed. It affords the patient the greatest protection, the greatest assurance against recurrence; and I think, as Dr. Fansler has said, that most people will come to the one-stage abdomino-perineal operation as the most desirable type of operation. However, I think that for most of us it is not a question of whether we should do the operation in one or two stages, but a question of accepting the one-stage abdomino-perineal operation or some lesser procedure, and I think that that is something that is sometimes overlooked in an effort to do what is the best thing for the patient without, perhaps, a careful inventory of our own capacity to do the necessary operation. I think that many times the patient would be better off with the lesser procedure than with the one-stage operation, but if the patient is of such type, so prepared that it is reasonable that he will withstand such an operation, there is no question but that it is the most desirable type.

Naturally, Dr. Fansler has spoken more in detail of the technic of surgery inasmuch as this is a surgical society. These people who have carcinomata of the rectosigmoid, I believe, require more careful preparation than almost any other type of individual. Dr. Fansler mentioned preparation by means of restoration of the hemoglobin, et cetera. I think many times we are too willing to accept, as was said, a hemoglobin of 50 or 60 and reassure ourselves a bit too readily by a simple transfusion. Many of these people are not only dehydrated, but are suffering from a food restriction and I believe that it isn't a question of one transfusion, but of multiple transfusions. These people need not only 500 or 600 c.c. of blood, but at times 1,000 or 2,000.

One thing that hasn't been stressed, although Dr. Fansler and I have talked about it previously, is the protein level in the debilitated patient. Many cases of rectal carcinoma, as a result of blood loss and restricted diet, will show a blood protein definitely below the normal level, enough below the normal level so that it constitutes a hazard not only to healing but to what is of equal importance, normal water metabolism. An individual with a plasmaprotein of 4 or 5 will not tolerate the same amount of fluid as a normal individual. This individual given 2,000 or 3,000 c.c. of fluid subcutaneously will develop edema in spite of anything that you do. The addition of chloride merely aggravates the condition.

Anesthesia, of course, is always a personal problem. As Dr. Fansler said, it is difficult for anyone to accomplish a one-stage abdomino-perineal excision with the ordinary novocaine spinal anesthesia. The anesthetic period is too short. One hesitates to reinforce it by a second spinal puncture, although I don't know whether this is a real hazard or not. This may be avoided by the use of metacaine, which gives a longer anesthetic period, but I do not believe that I would care to be confined to a given anesthetic time even with metacaine.

With regard to the technical procedure, I think Dr. Fansler might well emphasize the necessity for dissecting deep and separating the bowel much further than you think is ever going to be necessary, because it will probably never be too much and is often just about what is necessary to make the perineal operation simple and short.

The difficulty in closing the peritoneum, I would think, would be more of an apparent difficulty than an actual one if the dissection is begun by splitting the peritoneum high on the right side of the mesentery. There is always a long enough flap that can be carried over to the left side.

Like all operative procedures, this discussion could be carried on endlessly and perhaps with very little profit. It has been a pleasure to hear Dr. Fansler. I think he has had an excellent experience, I am sure as large as anyone here, and I think anyone who can present such a series and such a mortality is to be congratulated.

Dr. Lawrence Larson: Dr. Fansler deserves a great deal of credit for the manner in which he has presented his observations and the results he has obtained. Colon surgery is difficult, the mortality rate is high, and the end-results are not always too encouraging.

Several points in his paper are worthy of further emphasis. The first of these is that carcinoma of the rectum can only be cured by surgery, and if surgical cure is to be attempted, no half-way measures are permissible. There is ample evidence that malignant tumors of the rectum remain localized for a long period of time so that if adequate removal is accomplished, cure may be expected. It is with this in mind that operations involving wide excision of the growth, such as the combined abdomino-perineal resection method, are to be most highly recommended in the light of our present knowledge. This operation is comparable in its principles to wide resection of the lymphatics in carcinoma of the breast.

The greatest barrier to operability of rectal neoplasms is extension or metastasis of the growth, and that these tumors extend and metastasize late is a proved fact. In a series of 107 autopsies which I studied at the University of Minnesota, Department of Pathology, of rectal malignancies, about half died of the disease with either no extension or metastases, or with only a few regional glands involved. This is a fact of considerable significance since it gives encouragement in curing the disease even in a late stage if sufficiently wide resection can be done. Similar studies from surgical specimens show a frequent invasion of the regional glands but late distant metastases. Furthermore, many carcinomata, which at first observation seem inoperable because of extensive fixation to surrounding structures, in reality are operable. The fixation may be due mainly to inflammatory processes about the tumor. This is a commonly observed clinical fact and gives further encouragement in treating this disease. In addition, the size of the tumor has nothing to do with the degree of extension or metastases as shown by many studies, especially those of McVay.

All descriptions of the spread of carcinoma of the rectum indicate the most important is that in an upward direction along the course of the inferior mesenteric artery and thence laterally to the pelvic colon. Therefore, with this in mind, radical removal such as Dr. Fansler described definitely offers best opportunity for cure. Removal of the mesentery with its gland-bearing tissues even as high as that up to the sigmoid affords the best results.

Another factor to bear in mind is that rectal carcinoma is a rather common disease. In fact, about a third of all malignant tumors of the gastro-intestinal tract are in the colon, and more than half these cancers of the colon are in the rectum. It is because examination of the rectum can be easily and satisfactorily carried out by direct inspection or palpation, that, theoretically at least, we should diagnose these tumors at an earlier date, so that treatment could be more satisfactorily carried out. It goes without saying that much care should be taken in examining any individual who passes blood by rectum, or when there is an unexplained dyspepsia, weight loss, or change in bowel habits.

It seems trite to again emphasize preoperative preparation of these patients for surgery. However, if one is to widen the scope of this operation, there is only one way to make it applicable to a large number and that is to get these individuals in the best possible condition by a week or ten days of preparation. Obstruction can usually be relieved, the liver can be replenished with glycogen, any anemia improved and any cardiac or renal impairments treated. In this way, if two-thirds of the patients can be rendered operable, and if a mortality rate of 10 per cent or lower can be obtained, then we are approaching a satisfactory method of treating this disease.

Dr. Orwood J. Campbell: I have enjoyed Dr. Fansler's unusually lucid and commendable report of his experience with the one-stage abdomino-perineal resection. I want to say a word about what Dr. Fansler referred to as medical relief for obstruction.

For the past two years, I have been interested in the one-stage resection of carcinomas of the colon using an aseptic type of end-to-end anastomosis. Of course, this procedure cannot be done in the presence of any obstruction whatever. I have been surprised and gratified to learn how effectively incomplete obstruction can be relieved by placing the patient on the so-called nonresidue diet and giving large quantities of mineral oil orally.

I have had one case in which complete obstruction of the bowel was established due to a carcinoma of the sigmoid. X-rays revealed enormous gaseous distension of the ascending and transverse colon, with the descending colon distended and packed solidly with fecal material. The patient was in poor condition and during the several days which it took to get him into shape large quantities of mineral oil were administered, from 4 to 6 ounces per day. We had despaired of relieving him and on the 7th day prepared to do a colostomy. The obstruction was suddenly relieved and he passed large quantities of liquid feces. At the end of a three week period his condition was excellent and he was operated upon without any evidence of his previous obstruction. A single-stage resection with end-to-end anastomosis was done and he made a very satisfactory convalescence.

I think, if an effort is made to decompress an obstructed bowel "medically," considerable time may be required. While I do not recommend the attempt to relieve all cases of complete obstruction without preliminary colostomy or cecostomy procedures, it has been surprising to learn how effectively this relief can be obtained in many cases.

REPORT ON THE USE OF ROENTGEN RAYS FOR CONTRACEPTION

In 1932 Harris (Am. J. Roentgenol., 27:415, (March) 1932) and in 1936 Mayer, Harris and Wimpfheimer (J. Obst. and Gynec., 32:945, (Dec.) 1936) published articles dealing with the use of roentgen rays to produce therapeutic abortion. Their results were satisfactory, and they advocated this method as particularly desirable in cases in which surgery is hazardous or contraindicated for medical reasons. At the organization meeting of the Council's Committee on Contraceptives, it was suggested that roentgen rays had been used to cause sterility in women or to interrupt pregnancy for nonmedical reasons. Dr. A. U. Desjardins, in an effort to determine how extensively roentgen rays are being used for these purposes, wrote to twelve radiologists throughout the country. In all but one instance the replies from these men stated that they were not aware of such a practice, certainly on the part of reputable members of the profession, and were doubtful whether this technic was being employed to any appreciable extent by less scrupulous practitioners. (J.A.M.A., Nov. 5, 1938, p. 1767.)

BOOK REVIEWS

Books listed here become the property of the Ramsey and Hennepin County Medical libraries when reviewed. Members, however, are urged to write reviews of any or every recent book which may be of interest to physicians.

SURGICAL PATHOLOGY OF THE DISEASES OF THE MOUTH AND JAW. A. E. Hertzler, M.D. Surgeon to the Agnes Hertzler Memorial Hospital, Halstead, Kansas; Professor of Surgery, University of Kansas. 248 pages. Illus. Price, $5.00, cloth. Philadelphia: J. B. Lippincott Co., 1938.

A MANUAL OF FRACTURES AND DISLOCATIONS. Barbara Bartlett Stimson, A.B., M.D., Med.Sc.D., F.A.C.S. Assistant in Surgery, College of Physicians and Surgeons, Columbia University, New York City; Assistant Attending Surgeon to Presbyterian Hospital, New York. 214 pages. Illus. Price, $2.75, flexible binding. Philadelphia: Lea & Febiger, 1939.

PRINCIPLES OF HEMATOLOGY. Russell L. Haden, M.A., M.D. Chief of Medical Division of Cleveland Clinic; formerly Professor of Experimental Medicine, University of Kansas School of Medicine, Kansas City, Kansas. 348 pages. Illus. Price, $4.50, cloth. Philadelphia: Lea & Febiger, 1939.

SURGICAL TREATMENT OF HAND AND FOREARM INFECTIONS. A. C. J. Brickel, A.B., M.D. Departments of Anatomy and Surgery, Western Reserve University. 300 pages. Illus. Price, $7.50, cloth. St. Louis: C. V. Mosby Co., 1939.

TRAUMA AND INTERNAL DISEASE. Frank W. Spicer, A.B., M. D., F.A.C.P. 593 pages. Illus. Price, $7.00 cloth. Philadelphia: J. B. Lippincott Co., 1939.

ANNUAL REPORT OF THE SURGEON GENERAL OF THE PUBLIC HEALTH SERVICE OF THE UNITED STATES for Fiscal Year 1938. 184 pages. Illus. Price, 60c, cloth. Washington, D. C.: Government Printing Office, 1938.

PROCEEDINGS OF THE THIRTY-SECOND ANNUAL CONVENTION OF THE ASSOCIATION OF THE LIFE INSURANCE PRESIDENTS. 239 pages. Paper cover. New York: Association of Life Insurance Presidents, 1939.

AMERICAN ILLUSTRATED MEDICAL DICTIONARY. 18th ed. W. B. Saunders Co., 1938. 1607 pages. Illus. $7.50. Philadelphia.

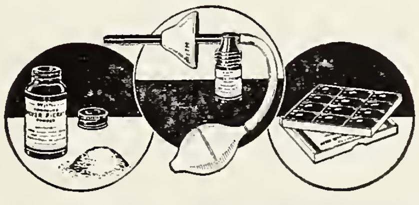
This new, revised edition brings up to date a standard dictionary which has always been a popular and helpful reference book. New terms have been added and many old definitions have been revised so that the book keeps up with the advances in medical science. Modernization of spelling, such as changing sulph- to sulf-, has been made and such new terms as sulfanila-

AN EFFECTIVE TREATMENT FOR

TRICHOMONAS VAGINITIS

An effective treatment by Dry Powder Insufflation to be supplemented by a home treatment (Suppositories) to provide continuous action between office visits. Two Insufflations, a week apart, with 12 suppositories satisfactorily clear up the large majority of cases.

JOHN WYETH & BROTHER, INC. • PHILADELPHIA, PA.



SILVER PICRATE — *a crystalline compound of silver in definite chemical combination with Picric Acid. Dosage Forms: Compound Silver Picrate Powder — Silver Picrate Vaginal Suppositories. Send for literature today.*

SILVER PICRATE • Wyeth •

mide have been added. The listing of proper names given to signs, diseases, glands, tests, under those general headings, aids in quickly finding the descriptions, especially if one is uncertain of the spelling. The derivations are not as fully or clearly given as they might be, but on the whole they are adequate.

Little change has been made in the arrangement of the book, the illustrations being scattered through the text and such tables as weights and measures being kept in their alphabetic place in the text. The Posologic and Therapeutic Table at the end of the alphabet has been changed to A Table of Dose in Both Apothecaries' and Metric System. By adding many more drugs and omitting the column "Action and Uses" this table is made more useful for quick verification of dosage.

As is true in nearly all dictionaries, some terms are omitted, and some definitions are not clear, but the fact that this reference tool has been so carefully revised and brought up to date compensates for the few disappointments it causes.

I. A.

THE HEART IN PREGNANCY. Julius Jensen, Assistant Professor of Clinical Medicine, Washington University School of Medicine, 371 pages. St. Louis; The C. V. Mosby Company, 1938.

In the book, *The Heart in Pregnancy,* Jensen has very ably gathered together all the information which is available in the literature relative to the heart and pregnancy. To this, he has added his own experiences which he has had in the St. Louis Maternity Hospital.

It may be interesting to know that Doctor Jensen secured some of his postgraduate work as a Fellow in Medicine in the University Hospitals at the University of Minnesota.

This book has been compiled so that the cream of the various subjects can quickly be digested, and, if a thorough knowledge of the subject is desired, one may obtain it by reading the whole.

The first section of the book considers the effect of pregnancy on the normal heart. He discusses the various theories, investigations and facts which have been presented to the medical profession on this subject in the past. One fact is striking and that is the relatively little valuable knowledge which we have regarding the heart and cyesis.

Jensen points out that there are many theories regarding various subjects by which we presume that there is an increased amount of work by the heart during pregnancy. Subjects such as an increased pulse rate, peripheral resistance, oxygen utilization, circulation time, cardiac output, et cetera, are still too little developed to be reliable. However, the most reliable information he believes is the increase in metabolism and the increased volume of the circulating blood which may be out of proportion to the increase in weight. He stresses the point that with the development of the x-ray, many new problems have been added to this question and few, if any, have been solved.

In the second section he discusses the abnormal cardiac impulse formation during childbearing such as tachycardia, brachycardia, extra systoles, auricular flutter and heart block.

The last section deals with organic heart disease and pregnancy. All angles of this extensive subject are presented and discussed. The importance of the relationship of heart disease to maternal mortality is a most serious matter and he very thoroughly presents all available information on this subject. He states that, "Heart disease ranks amongst the four or five most important causes of maternal death. It accounts, probably, for some seven per cent of all fatalities and claims close to 1,000 women per year in the United States," and, furthermore, "A death rate of 2-3 per cent appears to be irreducible at present, which means that the complication of heart disease and pregnancy carries a death rate at least three times as great as the present gross maternal death rate in the United States."

The chapters on the management of pregnancy in rheumatic heart diseases and the obstetrical delivery of cardiac patients are excellent and exhaustive.

Probably one of the most valuable parts of this book is his discussion of the relationship between eclampsia and permanent kidney damage, and the relationship between the so-called toxemias (with hypertension) and cardiovascular disease.

An extensive bibliography is also added to this book.

This treatise is so all inclusive that it becomes an invaluable aide to any one who practices obstetrics or cardiology, and I should like to add my personal gratitude to Doctor Jensen for the tremendous amount of work which must have been done to complete this study.—EUGENE M. KASPER, M.D.

DOCTORS, I SALUTE. Emilie Conklin. Price, $1.50. Light and Life Press, Winona Lake, Indiana.

A small volume of poems by the author, a few written on subjects allied to medicine; the majority on a variety of subjects.

As one reviewer said: "The volume seems to contain with few exceptions tributes in verse, rather than real poetic expressions. She (the author) seems to have said all she has to say about doctors in the first one entitled, "Doctors, I Salute!" Very little authentic emotion is evidenced in most of the others. What she tried to do, probably, was to dedicate a poem to each type of medical practitioner. That, I think, was a mistake. No one person could get all those different points of view well enough to have any feeling about them. . . . There are some lovely lines in "A Call to Service." "To Try on a Wall" is attractive.

To compare the author with Rudyard Kipling as was done by some reviewers, is in our opinion unjustified.—C.B.D.

THE "POSITION-RELIEF SYNDROME" OF HYDRONEPHROSIS*

JOHN M. BERKMAN, M.D., and JAMES T. PRIESTLEY, M.D.

Rochester, Minnesota

IN THE past decades innumerable laboratory procedures have been developed to augment the accuracy of clinical diagnosis. As a result, the detection of numerous organic diseases has been greatly facilitated and diagnoses, previously made largely by conjecture, can now be established with certainty. This remarkable development of mechanical devices has not been without its ill effects, however, as frequently we physicians may unconsciously practice "laboratory medicine" without giving sufficient time and consideration to careful study of the patient himself. This trend in diagnosis is well illustrated by the comparatively few articles dealing with clinical symptoms, syndromes, and observations made by physical examination that appear in the current medical literature. No amount of laboratory tests can ever supplant a carefully taken history and a thorough physical examination, although both are of course essential to the practice of good medicine.

Although a urologic diagnosis is ultimately made by the urologist, in some cases the internist plays an equally important part by his recognition of symptoms which to him suggest urologic disease. As a rule the internist's reasons for advising urologic investigations are based on the following three groups of factors: (1) gross hematuria, symptoms of vesical irritation, a mass or pain in the renal region referred to the region of the bladder and testes, and other symptoms which immediately suggest the advisability of cystoscopy or intravenous urography; (2) abnormal findings in the urine or roentgenographic evidence which suggests the possibility of urologic disease, or (3) atypical abdominal pain which has not been satisfactorily explained by the usual gastro-intestinal investigations, in which case urologic investigation is usually carried out only to make the examination complete. Such complete investigation is for various reasons frequently omitted.

Patients who consult numerous physicians because of abdominal pain or disgestive symptoms which cannot be definitely attributed to a given organ may sometimes be subjected to unnecessary operation, and finally they are considered to be neurasthenic and thereafter all symptoms are explained on this basis. Certain patients who have hydronephrosis are in this category. It is often well to remember, however, that the neurotic patient who presents a rather bizarre clinical story may have organic disease in addition to his nervous instability.

Lesions of the kidney which manifest themselves by definite urologic signs or symptoms afford little difficulty in diagnosis. Some patients who have an uninfected hydronephrosis, however, present none of the usual symptoms or findings, and in addition urinalysis and a plain reontgenogram of the kidneys, ureters, and bladder reveal no abnormality. These patients have usually had various diagnoses made and have received numerous forms of treatment without relief. In all probability the two factors primarily responsible for incorrect diagnosis have been failure to suspect the kidney because of an inadequate or unappreciated history and the opinion that a negative urinalysis and normal plain roentgenogram of the urinary tract exclude urologic disease. In cases of hydronephrosis other than those in which the kidney or renal pelvis is very large, it is very unusual to obtain diagnostic information from roentgenograms of the kidneys, ureters, and bladder without the use of a contrast medium. Likewise, if no infection is present urinalysis reveals no abnormality.

---

*From the Division of Medicine (Berkman) and the Division of Surgery (Priestley) of the Mayo Clinic, Rochester, Minnesota.

Since 1932 we have paid particular attention to a group of symptoms experienced by certain patients who have hydronephrosis which we have chosen to designate as the "position-relief syndrome." This syndrome is not presented with the purpose of advancing a new method by which an unquestioned clinical diagnosis of hydronephrosis may be made without further urologic investigation, but rather to call attention to a group of associated symptoms, heretofore not emphasized,* which in the absence of suggestive clinical and laboratory findings have shown themselves to be of very definite value in leading to a diagnosis of hydronephrosis. The patients observed in this clinic in whom elicitation of the position-relief syndrome has led to a diagnosis of hydronephrosis without exhaustive eliminating investigations have all had unilateral hydronephrosis caused by intermittent ureteral obstruction situated in the region of the ureteropelvic juncture.

The pain experienced by these patients is as a rule dull and aching. It is situated anteriorly in the upper part of the abdomen on the side of the involved kidney. The pain is usually not referred to the lumbar region or down to the region of the bladder or testes. This pain, or dull ache as it is usually described, is not definitely localized in the renal region but occurs in the entire upper portion of the abdomen. It may be more or less constant for several days, but it is usually present for a few hours or a day or two at a time and disappears only to recur at a later date.

Walking or standing in the erect position for a period of time considerably aggravates the pain. It is of interest to note that these patients as a rule awaken in the morning free from pain. After being up for several hours they may have a recurrence of the pain; however, most of their discomfort occurs later on during the day. Most of the attacks come on after a day's work and last throughout the evening. Definite relief is obtained by reclining. In the majority of instances more relief is obtained by lying on the back than on the affected side, and most relief is obtained by lying on the side opposite the affected kidney. In some instances patients have learned that attacks can be aborted by lying on the opposite side. In a very small number of cases** patients have obtained relief by lying on the affected side, more relief being obtained in this position than when lying on the side opposite the affected kidney, the latter position having increased the pain and caused a sensation of a heavy weight sagging down from the affected side. In these few cases this has been the only deviation from the described syndrome. Some patients have found that lying on the back with the arm on the affected side flexed under the lumbar region gives relief. Most of them, however, give a history of obtaining relief by lying on the unaffected side with a pillow placed under the lumbar region.

It should be emphasized that obtaining a history of the position-relief syndrome is not a simple matter and requires considerably more time and care than recording the usual history. Patients do not voluntarily offer this information, for in their opinion it is of no significance; consequently, careful interrogation regarding the postural relationships of their pain is important. Most of these patients have suffered for a period of two years or more and constant aggravation has lowered the threshold to pain to such a degree that they may appear as chronic complainers and such a diagnosis as neurosis or chronic nervous exhaustion may seem justifiable.

The accompanying reflex gastro-intestinal symptoms of loss of appetite and nausea also may appear to be neurotic in character. These two symptoms are very common. Loss of appetite may be rather marked, at times reaching such a point that very few foods are tolerated, resulting in considerable loss of weight. Nausea may occur periodically and last from a few moments to an hour or so, or in some instances it may be almost constantly present. It may recur without apparent reason several times daily, and it appears to have no relation whatsoever to the presence or absence of pain. While vomiting occurs, it is not nearly so frequent a symptom as loss of appetite and nausea. It is always associated with an increase in the severity of pain and usually is present only in the more severe attacks.

---

*It is common knowledge that patients with some diseases are more comfortable in certain positions than in others; however, we have been unable to find any record of this fact having been applied practically in the diagnosis of hydronephrosis.

**Several such cases of hydronephrosis were seen prior to the time when it was appreciated that the position-relief syndrome was common to many cases of hydronephrosis. We have no record of some of these early cases; however, we have a record of sixteen patients who gave a definite and unmistakable history of the syndrome. Two of these patients obtained relief by lying on the affected side.

Every patient who presents a history which suggests the position-relief syndrome will not have hydronephrosis; consequently, a certain number of unnecessary intravenous urograms may be made. The trouble and expense involved in cases of this type, however, are entirely compensated for by the discovery of a definite hydronephrosis in other cases. Early diagnosis by intravenous urography is most desirable, as then the kidney can usually be preserved. One should remember that ureteral catheterization in the presence of an intermittent obstruction at the ureteropelvic juncture may occasionally precipitate an acute obstruction which will require immediate surgical attention, especially if any infection is present.

The treatment of patients who have unilateral hydronephrosis of the type under consideration is primarily surgical. Whether a conservative operation on the renal pelvis and ureter is feasible or whether nephrectomy is necessary depends on the nature and extent of the lesion and the condition of the other kidney. Whenever possible, nephrectomy is avoided; however, in some instances the extensive damage of the involved kidney leaves no alternative. Commonly there is incomplete drainage from the renal pelvis which is caused by abnormal insertion of the ureter into the pelvis, narrowing of the lumen of the ureteropelvic juncture by fibrosis and thickening in the tissues in this region, compression of the ureter by anomalous vessels or fibrous bands, or possibly, physiologic abnormalities in the neuromuscular mechanisms which normally effect complete emptying of the renal pelvis. Depending on the nature of the lesion present the exact type of plastic operation most suitable for a given case will vary. These various surgical procedures will not be discussed at this time except to say that, when properly performed in well selected cases, quite satisfactory results may be anticipated.

A few illustrative cases are presented to indicate more clearly the value of the position-relief syndrome in establishing the diagnosis of hydronephrosis.

Cases Illustrating the Position-relief Syndrome

Case 1.—A woman, aged twenty-one years, registered at the clinic November 6, 1934, complaining of periodic, dull aching pain and tenderness in the left upper quadrant of the abdomen and momentary waves of nausea of four years' duration. She had experienced considerable gaseous indigestion associated with belching. Appendectomy had been performed, elsewhere, in June, 1933, without relief of symptoms. The pain usually lasted about two days, disappeared at night, and was followed by residual tenderness for two or three days. This distress was aggravated when the patient was on her feet, and she had discovered that definite relief could be obtained by reclining and that the pain disappeared within an hour or so after she lay on her right side with a pillow under her lower ribs, so that her left side was arched. Attacks of pain had occurred every three to six months, but had increased in frequency recently. There had been no fever, chills, or vesical symptoms.

On physical examination at the clinic the patient appeared healthy and examination gave essentially negative results except for slight tenderness in the epigastrium. Microscopic examination of a catheterized specimen of urine was entirely negative. Roentgenologic examination of the kidneys, ureters, and bladder without an opaque medium disclosed nothing abnormal. Because of the character of the distress, and in spite of the normal urinary findings, an intravenous urogram was made which disclosed hydronephrosis of the left kidney, grade 2 to 3, caused apparently by obstruction at the ureteropelvic juncture (Fig. 1). The right kidney was normal, and there was only slight reduction of function in the left kidney.

At the time of operation the left kidney appeared to be in good condition except for dilatation of the pelvis, grade 2 plus. The extrarenal pelvis was large and the ureter came off fairly dependently at the side of the pelvis closest to the vertebral column. There was no demonstrable cause for obstruction at the ureteropelvic juncture, which admitted a No. 10 French soft-rubber catheter without difficulty. A wedge-shaped area of the dependent portion of renal pelvis situated between the renal parenchyma and ureter was excised so that the ureter left the pelvis dependently and close to the kidney itself.

Following operation this patient was entirely free from symptoms for one year. At the end of that time she experienced pain over the left renal region which lasted for a period of ten days. This was associated with pus in the urine. Following marriage and pregnancy, pus was again found in the urine; however, no pain was experienced. Following delivery she felt very well, and she has been able to take care of her household duties without help and has had no pain whatsoever.

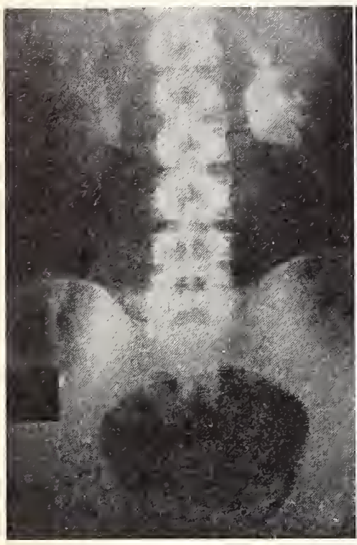

Fig. 1. (Case 1) Intravenous urogram, showing left hydronephrosis.

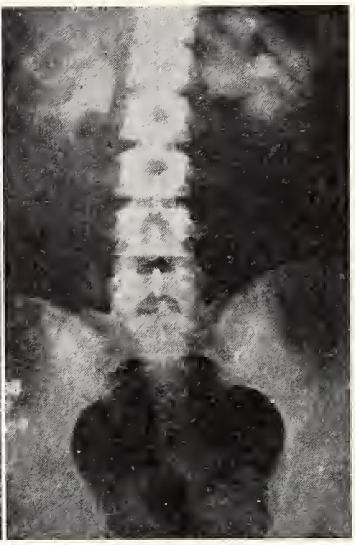

Fig. 2. (Case 2) Intravenous urogram, showing left hydronephrosis.

Case 2.—A woman, aged thirty years, came to the clinic in October, 1935, complaining of attacks of pain in the left upper abdominal quadrant of three years' duration. At first the pain had occurred at intervals of every two months and had lasted for a period of two days; however, during the previous year the attacks had occurred more frequently. The pain was dull and aching and would increase in severity for several hours, then gradually decrease and finally disappear. The attacks usually occurred in the afternoon. Numerous examinations failed to explain the pain, and the patient had been advised to take a vacation for two months, during which time she had two attacks. On returning to work, the attacks became more and more frequent and the severity of the pain increased. At this time with some attacks she began to experience nausea and vomited. Shortly before coming to the clinic the pain was present approximately five days out of each week and lasted two or three hours each time it occurred. At times the attacks occurred late in the morning, but more often in the afternoon, usually disappearing during the evening. There had been some loss of appetite, and gaseous indigestion had been a bothersome symptom; however, no loss of weight had occurred.

Careful questioning revealed that the patient obtained relief on reclining; lying on her back or her right side had aborted a number of attacks. She had found it impossible to lie on her left side as this position definitely increased the pain.

Physical examination and laboratory tests, including urinalysis and roentgenograms of the kidneys, ureters, and bladder, gave negative results. An intravenous urogram revealed left hydronephrosis, grade 3, which was considered to be secondary to obstruction at the ureteropelvic juncture (Fig. 2).

At operation the kidney appeared to be normal except for enlargement of the renal pelvis, grade 3. Several anomalous vessels ran to the lower pole of this kidney and pressed on the ureteropelvic juncture, thereby constricting the lumen of the upper portion of the ureter. The pelvis was of the square-shaped type, the ureter coming off at the medial dependent portion so that it was located a considerable distance from the lower pole of the kidney. After temporary constriction of the anomalous vessels, which did not demonstrate any marked circulatory changes in the lower pole of the kidney, the vessels were severed. A wedge-shaped portion of the lower part of the pelvis situated between the ureter and lower pole of the kidney was excised. This patient has had no symptoms whatsoever since surgery.

Case 3.—A woman, aged sixty-one years, registered at the clinic December 21, 1934, complaining of weakness, gaseous indigestion, and dull pain in the right half of the abdomen. The pain had occurred first about two years previously and had recurred periodically since then. It was referred sometimes to the region of the right scapula and occasionally was rather severe. Weakness had gradually supervened and the pain had become constant. Gaseous indigestion had become more pronounced and was especially troublesome after eating. Roentgenograms of the stomach and gallbladder had been made, elsewhere, and the patient had been told that she was suffering from disease of the gallbladder and was advised to undergo cholecystectomy.

Careful questioning elicited the fact that the pain was definitely affected by variations in posture. It was aggravated when the patient walked or was on her feet for any length of time. Lying on the back or right side gave her some relief, but lying on the left side gave considerably more relief. There had been no vesical symptoms, fever, chills, or jaundice at any time.

Physical examination was essentially negative except for obesity. Urinalysis was negative. Roentgenologic examination of the gallbladder disclosed that it was functioning poorly and contained stones. A roentgenogram of the kidneys, ureters, and bladder revealed no gross abnormality. Because of the definite postural relationship of the pain, and in spite of the negative urinalysis, negative roentgenogram of the kidneys, ureters, and bladder, and positive evidence of a diseased gallbladder containing stones, which could easily be accepted as the explanation of her symptoms, urologic investigation was carried out.

An intravenous urogram revealed a normal left kidney, and hydronephrosis, grade 2, of the right kidney. Cystoscopy and retrograde pyelography demonstrated marked stasis in the right renal pelvis, apparently due to obstruction at the ureteropelvic juncture (Fig. 3). Interestingly enough, following cystoscopic examination the patient had a slight reaction characterized by pain and fever. This responded promptly, however, to drainage of the right kidney with an indwelling ureteral catheter. The patient stated that the pain she had during this period was identical to that which she had experienced previously.

Operation revealed a small kidney firmly imbedded in inflammatory perirenal tissues. Marked pyelectasis and caliectasis were present, and the cortical surface of the kidney showed evidence of considerable infection. Because the patient was sixty-one years of age and the opposite kidney was normal, and because of the infection and extensive renal damage, nephrectomy was performed. The pathologist reported diffuse pyonephritis and multiple depressed scars on the cortex. The ureteropelvic juncture had been compressed by bands of fibrous tissue. It was estimated that 60 per cent of the kidney was destroyed. Following operation the pain entirely disappeared. The gastro-intestinal symptoms, however, did not improve. Two years later, cholecystostomy was performed and stones were removed from the gallbladder.

The following case is reported as an example of the small group of cases previously mentioned in which patients obtained relief by lying on the affected rather than on the unaffected side:

Case 4.—A woman, aged forty-nine years, came to the clinic in January, 1937, complaining of attacks of pain in the right side of the abdomen which had been present for a period of two years. At times, the pain had been referred through to the back. At first the attacks had occurred periodically and infrequently; however, in the year preceding admission they had occurred more frequently, and for the previous six months the pain had been almost constant. In this period of two years the patient had experienced periods of nausea, but these had had no relation to the presence or absence of pain. At first, nausea might be absent for a week or two at a time and then be followed by several attacks of nausea daily. In the year preceding admission these attacks of nausea had become more frequent and had occurred each day, and in the last six months the nausea had been almost constant. Loss of appetite was marked, and there had been an associated loss of weight amounting to 30 pounds (13.6 kg.). Because of the gastro-intestinal symptoms the patient had during these two years markedly limited her diet and for a few months preceding admission had eaten only soup. Vomiting occurred only when the pain was very severe. Various diagnoses had been made, one of which was appendicitis.

Careful questioning revealed that the patient had rarely awakened with pain in the morning. After being up for a time pain occurred, and she could obtain relief by reclining. While some relief was experienced when she lay on her back, most relief was obtained when she lay on her right side. She had made a small, square, thick pillow which she always placed under the right lumbar region. Lying on her left side always increased the pain and caused a sensation as though something heavy were sagging from her right side.

Physical examination was negative, as were laboratory tests, including examination of the urine and roentgenograms of the kidneys, ureters, and bladder. Urologic investigation revealed right hydronephrosis, grade 3, with obstruction at the ureteropelvic juncture (Fig. 4). At the time of cystoscopy 110 c.c. of residual urine was aspirated from the right renal pelvis.

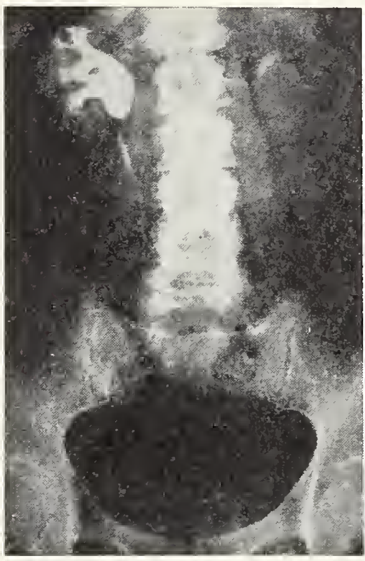

Fig. 3. (Case 3) Right retrograde pyelogram, showing hydronephrosis. (Retrograde pyelogram was made soon after an intravenous urogram.)

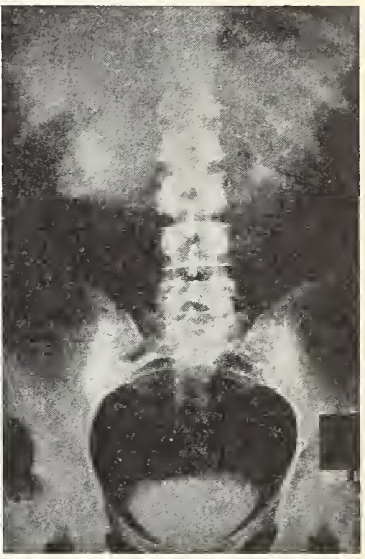

Fig. 4. (Case 4) Right retrograde pyelogram, showing marked hydronephrosis. (This pyelogram was made soon after an intravenous urogram, which showed diminished function of the right kidney.)

Operation revealed edema in the perirenal tissues and a large flabby-appearing kidney with a distended extrarenal pelvis the size of an orange. Dilatation of the calices had resulted in considerable thinning of the renal parenchyma. Hydronephrosis was associated with anomalous vessels running to the lower pole of the kidney. Nephrectomy was performed and the pathologist reported destruction of 50 per cent of the renal parenchyma.

The patient's convalescence was uneventful, and within a week from the time of operation she had a better appetite and ate more at each meal than she had at any time in the previous two years. The gastro-intestinal symptoms have entirely disappeared.

Summary

A certain group of patients who have uninfected hydronephrosis consult the physican because of abdominal pain which at first does not seem typical of any given organic disease. Urinalysis and a plain roentgenogram of the kidneys, ureters, and bladder reveal nothing abnormal. Careful questioning of the patient, however, elicits certain postural relationships of the pain to which the term "position-relief syndrome" has been applied. Anorexia and nausea are common associated symptoms.

This syndrome should, at once, arouse suspicion of hydronephrosis and indicate the necessity of urologic investigation. In most instances intravenous urography offers a very satisfactory method of diagnosis. Treatment is primarily surgical, and early diagnosis is most important before renal damage has become extensive, as this enhances the feasibility of a conservative operation and makes possible preservation of the kidney. If the disease is advanced, nephrectomy may be necessary. Four illustrative cases are presented.

WHY MEN KILL

Half the homicides committed in the United States arise over some trifling incident. This is the conclusion reached by a study of 500 homicides reported to the Metropolitan Life Insurance Company among a group of its policyholders. It may well be assumed that the same proportion applies to the total of about 10,000 homicides reported annually for the United States as a whole.

The information regarding the circumstances attending the 500 homicides covered by the present study has been obtained from such sources as reports of coroners' inquests, statements of insurance investigators, and newspaper clippings.

A great variety of situations—for the most part, absurdly trivial quarrels—led up to these misfortunes. Chief among these were disputes concerning domestic or family affairs: An irate husband beats and kills his wife because his dinner is not ready on time; a drunken youth shoots his mother for remonstrating with him about his drinking to excess; a man shoots a friend after an argument over being the last to be served a glass of beer in a neighbor's home. No less than 11.6 per cent of all the slayings follow domestic quarrels about no more serious affairs than these.

The second important occasion of quarrels leading to homicide involves money or property, usually of little value—sometimes no more than 25 cents. In still other instances, quarrels arise because of insulting remarks or personal affronts, gambling differences, or other situations that create a burst of hatred or anger. Typical incidents of this kind are the following: A lunchroom proprietor shoots a customer after an argument over the quality of a sandwich; a man is beaten and killed following a quarrel developing from a person's accidentally stepping on another's foot; a man slashes another because they quarrel about who shall play a mechanical nickelodian first. In a considerable number of these cases the abuse of alcohol is mentioned. Out of the 250 killings resulting from quarrels, in 116 cases either the slayer, the victim, or both had been drinking.

In connection with the homicides arising from jealousy or thwarted love, it is interesting to note that the beloved, and not the love rival, is more often the victim. Fifty-three persons were slain thus, as against 35 slain by their rivals in a love affair. In this type of homicide the slayer commonly commits suicide. In fact, one-fourth of the slayers who were classed as aggressors in the slaying of husband, wife, or lover ended their own lives also.

Homicides arising out of or during crimes of violence—robberies, burglaries, or jail breaks—account for 80 victims in this experience, or 16 per cent of the total number. Unfortunately, the officers of the law and law-abiding citizens are the victims more often than the criminals. Of 43 persons who died at the hands of felons, 6 were police officers; 15 were going about their work as watchmen, gasoline station operators, tradesmen, etc.; and the remaining 22 were other law-abiding citizens. The number of felons slain was 37, of whom 33 were killed by law officers and four by their intended victims.

Spectacular murders by gangsters constitute a lower percentage of the total than we should be led to expect from the publicity given to them. Only 14 of the 500 slayings, or under 3 per cent, fell into this class. These murders occur in connection with rackets involving the dope traffic, labor disputes, and lotteries, and usually arise from rivalry between gangs or the attempt of one gang to break into the territory of another.

Ten persons were killed in attempting to evade arrest for trespassing or for disturbing the peace. Eight were killed for revenge on account of personal grudges of long standing or from a desire to even scores against informers. Insane persons committed 14 slayings, of which six took place in institutions. In 11 cases no motive for the slaying was apparent: the slayer was crazed with liquor and had no particular enmity against nor quarrel with his victim. Apparently, at the moment, he merely wanted to kill. Of the three cases that are classified as due to miscellaneous causes, two involved sex offenses, and in one case the slayer killed his wife in despair over financial troubles.

Criminal abortions, of which there were 22 fatal cases, are included here to conform with the current international practice of statistical offices, which list this cause of death with homicides.

This review of 500 recent homicides brings out strikingly that practically all killings arise under the stress of emotions of fear, hatred, anger, jealousy, or greed. And, absurd as it may seem, by far the majority are due to disputes or quarrels about trifles. Surely under such conditions it should be possible to reduce the number of homicides to the point reached in other civilized countries.—*Statistical Bulletin, Metropolitan Life Ins. Co.*, January, 1939.

TREATMENT OF CHRONIC SUPPURATIVE DISEASE OF THE LUNG*

THOMAS J. KINSELLA, M.D.

Clinical Assistant Professor of Surgery, University of Minnesota Medical School

Minneapolis, Minnesota

THE term, chronic suppurative disease of the lung, is here used to include those more or less chronic, non-tuberculous, suppurative processes within the lung, included under the terms pulmonary abscess, pulmonary gangrene, pulmonary infarct, bronchiectasis, and, in addition, the chronic suppuration now being recognized with increasing frequency in the course of pulmonary tuberculosis secondary to bronchial stenosis and frequently inappropriately called tuberculous bronchiectasis. This group embraces a number of conditions which may be not only distressing, debilitating and very disabling to the patient but even quite annoying to his associates because of the foul sputum expectorated. Their course, complications, prognosis and treatment are not always thoroughly understood by specialists, and even much less so by the general profession who are called upon to treat so many of these patients. In general, taken by and large, they are not well handled. This presentation is made, not in the hope of answering all problems involved, for many are as yet unsolved, but rather to present some of the things we know about their care and the contributions which modern thoracic surgery has made towards their adequate treatment.

Pulmonary Abscess

There is always considerable confusion concerning the proper use of the terms pulmonary abscess and pulmonary gangrene, and as to when a plain pulmonary abscess becomes a gangrenous abscess. Perhaps the use of the terms non-putrid and putrid abscess might be less confusing, but even here no sharp lines can be drawn. The term gangrene is properly applied to a destructive process within the lung in which there is an associated group of various anaërobic organisms of the fusospirochetal group which produce the putrid odor characteristic of such conditions. The presence of such an odor is indicative of inadequate drainage and the presence of devitalized tissue or fibrin within the involved area. Following the removal of this material the odor from the abscess promptly subsides.

There is still much discussion as to whether pulmonary abscess occurs as a result of aspiration of material from the mouth or the lodgment of septic emboli in the lung field. This problem cannot be answered categorically but I believe it is only fair to state that it may develop in either way. Experimentally it is very difficult in normal animals to produce a lung abscess by injection of foreign material into the bronchial tree directly. The cough reflex is the protective mechanism of the lung which prevents such a development. It is quite evident that if an abscess is to be developed in this way there must be not only aspiration of septic material from the mouth or throat but there must likewise be some disturbance of this protective mechanism to permit retention of this material and obstruction of a portion of the bronchial tree before an abscess will develop. On the other hand, it is very easy, experimentally, to induce suppuration of the lung by the injection of septic material into a vein, from which it is carried to the lung, producing a small infarct in which the organisms may grow, producing the destruction characteristic of lung abscess. Clinically it seems evident that abscess within the lung in the human may be produced by both mechanisms. The abscess complicating a retained foreign body in the lung is an example of the first. A pulmonary abscess complicating an operation on a peripheral septic area is a good example of the second type.

Treatment.—While surgically we are more or less concerned with the more chronic stages of the process, a few remarks on the treatment of the earlier stages may not be amiss. The adequate use of bed rest, supportive measures, transfusion, maintenance of adequate nutrition and so forth cannot be stressed too strongly. The lung possesses marvelous powers of repair if it can be adequately drained and relieved of the offending material. The above mentioned measures may be expected to be followed by spontaneous evacuation and healing in a fair percentage of instances. Medications of various types may be of some value, particularly expectorants, sedatives to control excessive cough but not to suppress the cough reflex. Antipyretics, analgesics and so forth may also add to the patient's comfort. Arsenic and bismuth injections have been used rather extensively in the hope of destroying the causative organisms, thereby healing the abscess. These drugs may have some value in helping to control the odor by killing the putrefactive organism present, but unless the abscess is drained adequately and the dead tissue removed the odor will recur. Sulphanilamide may be of some value if streptococci predominate. They should not be considered as curative drugs in this condition.

---

*Presented before the Southern Minnesota Medical Association, Rochester, Minnesota, September 29, 1938.

Postural drainage has a definite and valued place in the treatment of various pulmonary diseases, but it must be used intelligently and not merely as a routine. Unless an abscess is draining through a bronchus, and that fairly freely, it is foolish to expect postural drainage to help the situation. Many a patient desperately ill with suppuration within the lung has been needlessly subjected to postural drainage when the abscess did not as yet have a communication with an open bronchus. Postural drainage only utilizes gravity in the drainage of an unfavorably located abscess through its communicating bronchus, which means turning the patient to such a position that the opening of the draining bronchus is at the bottom of the abscess cavity so that the pus may enter it and be coughed up. By the same token it is folly to utilize postural drainage when preceded by large doses of opiates which render the cough reflex inoperative. This not only interferes with adequate drainage but may predispose to aspiration and retention of septic material in other areas of the lung.

Bronchoscopic Examination and Aspiration.—It is not my province to attempt to discuss bronchoscopic treatment of pulmonary suppuration. A few points, however, are pertinent. It should not be done immediately but rather delayed until an abscess wall has formed and the abscess localized, a phenomenon which usually occurs in about three weeks. If no results are obtained after two or three such treatments it should be discontinued and another type of treatment instituted. While its greatest field lies in the treatment of acute abscess it is eminently worth while in the treatment of chronic abscess and a goodly number, even several months old, may clear completely following the establishment of adequate drainage by bronchoscopic methods. Good effects come, not from the passage of the bronchoscope itself, but from the establishment of adequate drainage from the abscess through a free bronchus by the dilatation of strictures so commonly present in lung abscess, by removal of obstructing granulation tissue, by removal of foreign bodies, and by the removal of dead tissue from the abscess cavity itself. The removal of tissue from the obstructing area for microscopic examination at the time of bronchoscopy cannot be too strongly stressed, as 10 per cent of chronic lung abscesses develop distal to a degenerating malignancy of the bronchus which might otherwise be missed. The valuable aid which the bronchoscopist may give in the localization of the abscess must not be overlooked.

Aspiration.—I mention external aspiration in speaking of treatment of pulmonary abscess merely to condemn a practice all too commonly used in the presence of this type of pulmonary suppuration. It seems to me that almost every abscess I have seen recently has either been needled or such a recommendation has been made before considering surgical drainage. Don't do it. The practice is dangerous and at the best cannot hope to cure the condition. In the first place these abscesses contain not only pus, but fiber masses, clots and dead tissue, which not only could not be aspirated through the ordinary needle even of veterinary proportions, but could not be pulled through the ordinary catheter, so the chances of accomplishing anything by such aspiration are nil. Secondly, there is danger of inducing hemorrhage, air embolism, or metastatic foci by such manipulation. Thirdly, and by far the most important: While the presenting point of the abscess towards the pleura may be surrounded by adhesions and therefore walled off from the free pleural cavity there are all too frequently extensive areas of free pleural space adjacent to this point so that the exploring needle may not only cause air leakage into the pleural cavity resulting in accidental pneumothorax but it may cause a rupture of the abscess into the free pleural space or contamination of the intact pleural cavity by the myriads of organisms present in the abscess and adjacent lung tissue as the needle is withdrawn across the obliterated space. One has only to be called upon to see, or smell or treat a putrid empyema resulting from such an attempt to forever be cured of such a practice. The aspirating needle should be inserted into the lung or abscess cavity only at the operating table with the pleura exposed as the abscess is about to be surgically drained.

Artificial Pneumothorax.—Again I mention a procedure which should not be advocated in the treatment of pulmonary abscess, for it, likewise, is dangerous. The chances of a successful result from its use are not particularly great. We should expect no results from its use unless the bronchus were patent and the abscess draining freely, and then it should not be necessary, for under such conditions the abscess will usually heal spontaneously. Pneumothorax can do nothing save squeeze down the lung in an attempt to approximate the walls of the abscess cavity. Unless there is adequate drainage for the necrotic material present in the abscess, the walls cannot be brought into apposition and the collapse of the surrounding tissue may well interfere with rather than favor drainage through the bronchus. Likewise, there are usually some local adhesions about the peripheral point of the abscess which will prevent complete collapse of the involved lobe, and pulling upon these adhesions by increasing intrapleural pressure may well tear through infected tissue, cause a perforation of the abscess into the free pleural cavity, or contamination of the pleura without rupture of the abscess directly. A violent, putrid empyema resulting from such contamination may be extremely serious if not fatal to the patient.

Localization of Abscess.—Accurate localization of the position of the pulmonary abscess is essential to both medical and surgical treatment of the condition. To the medical man it is important in the selection of a proper posture to facilitate drainage after the bronchus is open. To the surgeon, considering external drainage, it is of even more vital importance, for his approach should be made over the most superficial point of the abscess to avoid the necessity of traversing lung tissue to reach it. Localization of the abscess may be accomplished by several methods or a combination thereof. First, the occurrence of a local area of pleurisy may indicate the presenting point of the abscess cavity against the parietal pleura. Second, the finding of local point tenderness in the interspace may very sharply localize the position of the abscess, an indication of local pleurisy and hypersensitivity of the parietal pleura in this area. Physical examination by percussion may accurately localize the process or the stethoscopic findings of consolidation or cavitation may be of help. True cavity findings are encountered much less frequently than in tuberculous cavitation, probably because of the more frequent occurrence of bronchial narrowing in these suppurative conditions.

Bronchoscopic examination may be of great value in localization of an abscess by indicating from which bronchus or bronchial radical the pus from the abscess appears. A blocked, branch bronchus or area of granulation tissue may be the sentinel to indicate the position of the communicating bronchus. A word of caution might be inserted to avoid an occasional mistake which can easily be made if local conditions are not taken into account. An abscess which lies adjacent to an interlobar fissure may penetrate this fissure and drain through a branch bronchus of an adjacent lobe, thus pus may be seen coming from a small branch of an upper lobe bronchus whereas the main abscess originated within the lower lobe.

Roentgen examination, of course, offers a very accurate method for localization of the pulmonary pathology. Exposures taken in the posterior-anterior and lateral direction will usually give a better localization of the process than will stereoscopic plates. It is usually advisable to accurately localize the abscess at the earliest possible moment, as subsequent thickening of the pleura or the development of a pleural effusion may later render such localization by x-ray difficult or impossible. The recent developments in tomography or planography have proven of great value in this type of work, particularly in the presence of thickened pleura, pleural effusion and multilocular abscesses where a fluid level with an air pocket above are not present to give sufficient contrast to be easily seen, particularly on the lateral exposure.

Treatment.—(1) Diaphragmatic Paralysis: The use of phrenic nerve interruption to paralyze the diaphragm in the treatment of pulmonary abscess has been advocated from time to time but has never become particularly popular and probably should not be. If the abscess is adequately drained through a bronchus and some help is necessary to bring about approximation of the abscess cavity walls then perhaps phrenic interruption might be of use. However, caution should be used, and it must always be remembered that paralysis of the diaphragm may be followed by excessive elevation and subsequent kinking of the draining bronchus and interference with drainage of the cavity. It might, therefore, increase rather than alleviate the difficulty. It must never be used unless the bronchus is widely open and the abscess adequately drained.

(2) Thoracoplasty: For the same reasons mentioned above, the use of extrapleural thoracoplasty in the treatment of these conditions is not to be advocated unless the abscess is adequately drained and some additional help is needed in the closure of a rigid walled residual pocket. Under these conditions the use of extrapleural thoracoplasty to reduce chest volume and approximate cavity walls, or obliterate empyema cavity, might be advantageous. Here, as in phrenic nerve surgery, unless the abscess cavity is adequately drained, extrapleural thoracoplasty should not be used, as it may bring about kinking of the bronchus and interference with drainage.

Extrapleural Plombe or Packing.—The use of some form of extrapleural packing following the stripping of the parietal pleura from the inside of the chest wall surgically, either in the form of gauze or a paraffin mass, has been advocated and used in the treatment of pulmonary abscess. Theoretically, in the presence of a peripheral abscess, adequately drained through its bronchus, the application of external pressure in the region of the abscess wall should be of aid in obliterating the residual cavity. Some good results have been obtained by the use of this procedure in properly selected cases. It should not be used unless the abscess is draining adequately through the bronchus, and by the same token should not be used in the treatment of putrid abscess when the very nature of the discharge indicates that the cavity still contains a necrotic tissue which must be removed. In a modification of this procedure advocated by Dolley, packing material is placed outside the parietal pleura and periosteum following resection of the overlying ribs. It is well to remember here as in the corresponding treatment for peripheral tuberculous cavities that at times the peripheral shell of the lung overlying the cavity survives only through a blood supply acquired through the adhesions formed between visceral and parietal pleura, and that when the pleura is stripped from the chest wall for the insertion of the plombe, the blood supply is destroyed and necrosis of the cavity walls may occur from pressure or the rupture of the abscess into the pack bed. Extrapleural paraffin has likewise been used by Sauerbruch as the first stage in the drainage of pulmonary abscess, the irritation stirred up by its presence causing obliteration of the adjacent free pleural cavity. The pack is then removed and the abscess drained into the pack bed at subsequent operation.

Surgical Drainage.—The question as to which pulmonary abscesses should be drained and when they should be drained is one which cannot be settled arbitrarily, as individual conditions, location, experience and facilities available must be taken into account. Extensive figures have been compiled and published showing the comparative results and mortality of medical and surgical treatment of lung abscesses, both nonputrid and putrid, all of which are very confusing and after all may not mean much unless the extenuating circumstances in all cases are taken into consideration. First of all, pulmonary abscess and pulmonary gangrene are extremely serious conditions. The patients are desperately ill from a marked toxemia and a goodly number die before the process ever becomes localized. This is especially true in the putrid condition called pulmonary gangrene. Should the patient survive the acute process he is still desperately ill from an extremely serious condition. Supportive treatment with a minimum of external trauma should be the keynote at all times. When the process has become localized at the end of three weeks or thereabouts more active measures should be undertaken, using the simpler means first and the more radical only when they become indicated. If the process is clearing spontaneously and improvement is progressive, certainly no active interference should be undertaken. If it is not, bronchoscopic examination and treatment should be instituted in an attempt to obtain early adequate drainage of the abscess through the bronchus. If this can be accomplished the patient may be saved much more serious interference at a later date, and the duration of his illness may be vastly shortened. If this proves inadequate, either because entrance to the abscess cannot be obtained or because adequate drainage does not follow, the treatment should be discontinued, for it is folly to subject the patient to a whole series of procedures which are not producing the desired results. Needless to say, the manipulation should be gentle as possible and not performed by a beginner at this type of work.

If favorable response has not been obtained from the previous treatment, the question of surgical drainage of the abscess must be considered. The questions of when and how are often extremely important. There is firmly rooted in the medical mind the idea that no surgical attempt at drainage of pulmonary abscess should be undertaken within three months of the onset, and all too frequently this period is extended indefinitely in the hope that a miracle will occur and the abscess heal spontaneously. All of this was very well in its day, when thoracic surgery was in its infancy, but today the problem is much different. Manifestly, there is no excuse for surgical interference for a lung abscess which is healing spontaneously. Likewise, an abscess which is improving and receding under bronchoscopic aspiration should be allowed to continue to do so as long as the improvement is progressive and complete. Should this not result, surgical drainage should be considered. Pulmonary abscesses begin to heal when adequate drainage is instituted. They do not heal when there is inadequate drainage, when there is necrotic tissue present giving the putrid odor, when they are multilocular, which usually means inadequately drained, and when they have persisted for such a time that the wall becomes rigid and the lung fibrotic with secondary bronchiectatic changes in the adjoining tissue. If the pus and necrotic tissue cannot be removed through normal channels then drainage must be established by surgical means. Much of the high mortality attributed to surgical drainage of lung abscess may fairly be attributed to delay in submitting the patient for surgical drainage rather than to do the surgical manipulation itself.

Delay in establishing adequate drainage may permit the process to become multilocular, metastasis to occur, the pleural cavity to become infected or the patient to become so debilitated only a miracle could save him no matter what be done. It is true that there are certain definite dangers associated with operations for surgical drainage of the lung abscess, some of which can be minimized, some of which cannot. The dangers of shock and hemorrhage can be reduced by proper pre-operative and operative manipulations and the use of certain technical steps not pertinent to this paper. The danger of the development of an empyema can be greatly reduced by the use of a two-stage operation but cannot be totally eliminated. The danger of air embolism can be reduced but not completely prevented. The dangers of local spread of the disease can be lessened by avoiding heavy doses of sedatives which might hinder expectoration postoperatively. The danger of metastatic peripheral abscess which occurs spontaneously and which may be induced by local manipulation cannot be avoided.

The question as to whether to use a one-stage or two-stage drainage of a lung abscess can be settled rather simply. If the pleural cavity is completely obliterated in the exposed area, a single-stage drainage of the abscess may be undertaken, with approximately the same degree of safety as a two-stage operation, except for those abscesses which lie under the scapula and necessitate extensive discretion for proper exposure. In such a case it may be wiser to insert a pack to wall off the local area before grossly contaminating it with the myriads of organisms always present in these abscesses. If free pleural space is present, mere suturing of the lung to the chest wall may prove adequate to permit a one-stage drainage of an abscess but is quite likely not to do so, and secondary infection of the pleural cavity may result. Two-stage drainage of lung abscess is undoubtedly safer because it permits the walling off of the pleural cavity and the adjacent tissues before the inevitable contamination which must follow opening of the abscess into the local field. Even if the lung appears to be fused to the parietal pleura, it may be well to place an encircling suture in order to be sure that the manipulation of drainage of the abscess and subsequent packing does not tear down delicate adhesions and permit the adjacent pleural cavity to open.

With the field exposed, the local area is palpated to localize the abscess, an exploring needle is inserted and the abscess opened along the needle before it is withdrawn. While the making of a small opening for the insertion of a small tube may at times prove adequate it is not to be recommended. The opening should be made sufficiently large to permit exploration of the interior of the cavity, to permit the removal of devitalized tissue and a visual search for the openings of accessory pockets, particularly in those abscesses which have never shown a single fluid level on x-ray films. Following the removal of a necrotic tissue, which must be done gently to avoid producing hemorrhage, the cavity is packed with gauze to control any oozing. Stiff-walled tubes should not be inserted for fear that they may produce a slough of the lung tissue with subsequent hemorrhage. The external opening must be kept open until the abscess cavity has become obliterated by expansion of the surrounding lung or by granulation tissue if recurrence is to be avoided. It is to be expected that the process of healing will be slow, particularly in those abscesses which have existed for a long period of time prior to drainage. Secondary plastic closure by pedicle muscle flaps may subsequently become necessary but should not be done until all infection in the surrounding lung tissue has subsided. The recently published work of Neuhof, Mount Sinai Hospital, New York, on the early drainage of putrid lung abscess by surgical means is worthy of note, and may prove the answer to avoiding prolonged disability so frequently associated with this disease and its treatment.

Lobectomy.—This procedure has not been given particularly serious consideration in the treatment of lung abscess until the last few years because of the relatively high mortality associated with this operation in the earlier stages of its development. With the advances which have been made in thoracic surgery in the last few years and the lowered mortality which has come with greater experience in this field, it is now proper to at least consider the possibilities of lobectomy as a proper surgical treatment for certain lung abscesses of more chronic type. In this category might be included the chronic abscess from which the patient is having profuse or repeated pulmonary hemorrhage, the abscess with a more or less rigid wall which might be obliterated with difficulty after external drainage, and the chronic abscess associated with considerable bronchiectasis. The pleural cavity should not be too densely obliterated but a partial obliteration of the pleural cavity should render the procedure less hazardous. One of the cases presented in the lantern slide demonstration accompanying this paper illustrates this point. In this instance, the patient presented a more or less chronic right lower lobe abscess from which profuse pulmonary hemorrhage had occurred on several occasions. The pleural cavity was almost completely free of adhesions. A primary, one-stage, right lower lobectomy was performed in preference to a two-stage drainage of the abscess with a very favorable result. The question of the relative risk of the two procedures, of course, must always be borne in mind.

Bronchiectasis

Bronchiectasis is a condition and not a primary disease. It may develop on a congenital background but more commonly occurs secondary to a number of conditions such as pulmonary abscess, intra-bronchial foreign body or tumor, tuberculosis or a number of other conditions in which association of infection with bronchial stenosis or some other disturbance of bronchial drainage leads to weakening of the bronchial wall, dilatation and cavity formation, with the production and retention of various amounts of secretion in the involved area. This condition is essentially a chronic one whose early course is often mild and characterized by periods of complete or relative absence of symptoms. The early symptoms are those of a recurrent chronic bronchitis, while later there is more or less constant cough with expectoration of varying amounts of purulent sputum which may be foul or putrid if retention of secretion occurs. Intercurrent episodes of pneumonia or pneumonitis are relatively frequent. Pulmonary hemorrhage varying from slight streaks or pinkish sputum to repeated or profuse pulmonary hemorrhage occurs in at least one-half of the patients so afflicted, more frequently on a percentage basis than in patients suffering from pulmonary tuberculosis. Later in this disease, dyspnea, cyanosis of the lips, cheeks and digits occurs frequently and clubbing of the fingers and watch crystal nails are frequently seen. It may be compatible with life for long periods of time, although the recurrent attacks of pneumonitis are quite dangerous. In the earlier stages of the disease, the cough is more of a nuisance than a handicap, whereas in its later stages the frequent cough and profuse expectoration, particularly if associated with foul odor, is a serious handicap, interfering with work and more or less ostracizing the patient from his family and associates.

Diagnosis.—Before the advent of bronchoscopic examination and radiographic study following the injection of iodized oil into the bronchial tree, our knowledge of this condition was more or less confined to the advanced stages of the disease where the classical picture of the disease was all too evident. With the aid of these measures, it is not only possible to detect the condition in its earlier stages but to clearly outline the extent of involvement and the changes which may occur from time to time during the course of the process. Such information renders our attempts at treatment of the condition, particularly by surgical methods, more accurate and altogether more satisfactory. Before any intelligent attempt can be made at the treatment of this condition, it is absolutely essential that these studies be made and the exact extent and character of the local condition known.

Treatment.—Efficient treatment of this condition must, of course, vary with local conditions, the extent and duration of the process and the presence or absence of associated complications.

1. Constitutional Treatment: While these patients are frequently of fair nutrition, they are usually below par in more ways than one. Rather intensive hygienic treatment associated with an adequate amount of rest is usually indicated in order to improve the patient's general condition and his resistance against the infection which he is carrying. Special treatment may be required because of poor appetite, anemia, digestive disturbances, etc.

2. Respiratory Infection: As these patients are usually unduly susceptible to upper respiratory infections, they must be protected against these infections to the greatest possible degree by avoiding contact, avoiding exposure, the use of cold inoculations and other measures designed to avoid or minimize the effects of these infections upon the individual. Active treatment of even slight upper respiratory infections is to be advocated to minimize their severity or the possibility of their extension to the lung.

3. Sinus Disease: The majority of these patients are suffering from chronic upper respiratory disease with involvement of one or all of the sinuses, infected tonsils, etc., and special attention should be directed toward the treatment of these conditions, not in the hope that by relieving the patient of his upper respiratory trouble the damage already done to the lung will be corrected, but rather in an attempt to render the individual less susceptible to frequent infections, and to stop or at least slow up the progress of the condition in the lung.

4. Change of Climate: If the individual suffering from bronchiectasis lives in a climate in which respiratory infections are frequent and changes in weather are marked and severe it may be well to advise a change of climate to one more mild or less rigorous in the hope that a diminished number of upper respiratory infections may benefit the patient and his bronchiectasis. It is illogical to expect such a change in climate to cure the condition but such a change may be important in the alleviation of symptoms.

5. Drugs: The use of drugs of various types, cough mixtures, both sedative and expectorant, may be of some value in symptomatic control or in facilitating expectoration. They may be an aid in keeping the patient comfortable and rendering his expectoration less difficult or helping to relieve odor, but it is to be considered palliative and not curative. The use of arsenic and bismuth may in some instances help to reduce the foul or putrid odor of the sputum but in no way affects the original condition, merely inhibiting the growth of certain putrefactive secondary organisms.

6. Postural Drainage: Postural drainage is of definite value in the treatment of bronchiectasis. It is not curative in any sense of the word, but it may help the patient to raise his sputum with less effort or at stated times rather than continuously, and by facilitating drainage and eliminating stasis it may be a great factor in reducing the fetor of the sputum, thereby rendering the individual less obnoxious to his associates. The proper position to be used must be determined by experiment and utilized faithfully if the patient is to derive the greatest benefit from it.

7. Bronchoscopic Manipulation: Bronchoscopic examination and treatment may be of definite value in bronchiectasis by localizing the process, by detecting the presence or absence of stenosed bronchi, by permitting the discovery and removal of offending foreign bodies or obstructing tumor tissue, and by opening stenosed areas to promote more adequate drainage. The use of repeated bronchoscopic examination or lavage of the bronchial tree would seem to be of questionable value in treatment aside from the more adequate drainage effected by the manipulation and dilating of strictures.

8. Collapse Therapy:

(a) Artificial Pneumothorax: While occasionally, in early bronchiectasis, the use of artificial pneumothorax may seem to be followed by definite and rather lasting improvement from the symptomatic standpoint, it should be emphasized that collapse of the lung by artificial pneumothorax does not as a rule bring about a closure of the bronchiectatic dilatation because of the intrinsic rigidity of the bronchial walls. For the control of hemorrhage from the lung, the use of artificial pneumothorax in bronchiectasis may be equally as efficient as in pulmonary tuberculosis, where it is of proven value. The dangers of secondary infection of the pleural cavity from the infection within the lung cannot be overlooked and offers a very potent argument against the use of this treatment, particularly in the more advanced stages of the disease.

(b) Phrenic Nerve Surgery: Paralysis of the diaphragm on the affected side occasionally is followed by improvement in symptoms but is not to be recommended for frequent use, as the elevation of the diaphragm which occurs is quite likely to bring about change in position and angulation of certain of the bronchi of the lower lobe and frequently is followed by interference with drainage rather than improvement thereof.

(c) Extrapleural Thoracoplasty: The use of extrapleural thoracoplasty for the treatment of chronic bronchiectasis may be followed by some reduction in both cough and expectoration, but the results obtained thereby in no way compare with the favorable effect obtained by the use of the same method in the treatment of pulmonary tuberculosis. If one is to be satisfied with partial reduction in symptoms, then at times the procedure may be worth while; but in spite of the collapse obtained, the bronchiectatic dilatation remains, the rigidity of the abscess walls preventing collapse as the chest wall is compressed, and secretion is still produced and expectorated. It is possible here, as in the use of phrenic nerve surgery, that the change in position brought about by the collapse obtained may at times seriously interfere with the drainage from the involved area.

9. Cautery Lobectomy: The use of cautery lobectomy as advocated by Graham a number of years ago has never become particularly popular and is not utilized very widely in the treatment of chronic bronchiectasis. It should be used only where the pleural cavity is obliterated. The destruction of the peripheral portion of the lung produced by the cautery creates external drainage for the bronchiectatic areas by the creation of multiple bronchial fistulæ. Through these the secretion formed in the involved area drains to the outside rather than being coughed up, thereby reducing the amount of cough and expectoration and perhaps reducing the foul odor by avoiding stasis. Continuous and prolonged drainage is necessary if any benefit is to be derived from it. The dangers of hemorrhage and embolism must be understood and the necessity for daily dressings for a long period of time realized before the procedure is undertaken. The field of usefulness has been diminished greatly by the more modern advances in lobectomy and pneumonectomy.

10. Lobectomy: The surgical treatment of bronchiectasis carries with it an element of risk

which, while it has been greatly reduced in the past few years, is still sufficiently great to engender caution in the selection of patients to be subjected to this type of treatment. Under no circumstances should it be undertaken too lightly. The degree of bronchiectasis present and the symptoms produced by it must be sufficiently severe and disagreeable to the patient to warrant the risk involved in the surgical extirpation of the lesion. If the lesion is unilateral and confined to one lobe and is producing symptoms sufficient to justify the risk entailed, then surgical extirpation of the involved area offers a means of ridding the patient of the diseased tissue in its entirety and should be considered. While the details of this surgical procedure are not pertinent to this paper, they should be reviewed by anyone considering the recommendations of such a procedure, so that a balanced judgment of the procedure and its possibilities may be obtained. Lobectomy in one or two stages may be performed, depending upon the obliteration or freedom of the pleural cavity, with possibly slightly less risk present where the residual lobe is already adherent to the chest wall. Postoperative bronchial fistula and localized empyema are a frequent occurrence following this procedure and somewhat delay the complete recovery of the patient. They do, however, eventually heal. There is a small field for the use of bilateral lower lobe lobectomy but steps in this direction are to be undertaken rather cautiously because of the known tendency of the process to slowly progress and involve adjacent lobes at a later date. The patient's residual vital capacity and working capacity must be taken into consideration before deciding upon such a procedure. Lobectomy may be performed both in children and adults and will undoubtedly become a more common operation as a greater knowledge of its possibilities develops.

11. Pneumonectomy: Certain extensive cases of bronchiectasis, either congenital or acquired, can only be successfully treated by the removal of the whole of the involved lung. This constitutes a very drastic step in the treatment of such a condition, but, under the circumstances, it is at times the only thing which can be offered to the individual to relieve him of an extremely distressing condition. Removal of the whole lung for suppurative disease undoubtedly carries with it greater risk than total pneumonectomy for primary malignancy of the lung, because of the associated extensive infection and greater danger of contamination of the pleural cavity. It is, however, to be considered and has been carried out successfully in a number of instances in this country. The risk, of course, is materially greater than that of lobectomy but may be amply justified by the extremely extensive disease which necessitates such a radical intervention.

Secondary Bronchiectasis Developing During the Course of Pulmonary Tuberculosis

During the past few years, more intensive study of the tuberculous individual and the more frequent use of bronchoscopic examination and iodized oil instillation into the lung in the patient suffering from pulmonary tuberculosis has brought to our attention the relative frequency of bronchial stenosis and secondary atelectasis and bronchiectasis in the tuberculous lung. Since we know of the existence of such a condition, we look for it and find that it is not a rare condition but one which develops under our eyes fairly frequently during the course of this disease. Apparently ulceration of the bronchus is followed by the development of granulation tissue in the ulcer base and this in turn reduces the bronchial lumen, giving a partial or even complete obstruction. Obstructive emphysema or atelectasis develops, depending upon the degree of obstruction present, whether the stenosis has merely narrowed the lumen or produces a check valve or a stop-valve in the bronchus involved. Periodic retention of secretion with sepsis follows if secondary infection is present. If not, simple atelectasis may supervene with a permanent loss of function of the involved portion of the lung. Distal to the stenosed area, secondary bronchiectasis develops very frequently and may be either a non-productive or productive type. To this condition the term "tuberculous bronchiectasis" has at times been applied but it is apparently the same type of bronchiectasis which develops in a non-tuberculous lung under similar circumstances. It is bronchiectasis developing in a tuberculous lung, associated with tuberculosis but not a characteristic part of the tuberculous picture. Bronchiectasis without bronchial stenosis may also be seen in a tuberculous lung as a result of the extensive fibrosis and retraction which occurs in the healing of a tuberculous process.

Both of these types of bronchiectasis in the tuberculous lung may account for persistent cough and expectoration with negative sputum or amounts of sputum out of proportion to the amount of active tuberculous involvement. The use of collapse therapy has been held forth as the cause of the development of bronchiectasis in the tuberculous lung but I do not believe that its use *per se* is responsible for these difficulties. They occur in the tuberculous lung without collapse therapy just as well as during the procedure. Frequently, if a thorough investigation is made it will be found that symptoms suggestive of this type of involvement were present before the collapse therapy was undertaken but were overlooked at the time. Ulceration and stenosis of the above mentioned type may occur any place in the tracheal system. Cases of tracheal stenosis, stenosis of the primary bronchi and any of the secondary bronchi have been observed. Both upper and lower lobe involvement is seen. The process in our experience is far more frequent in females than in males. The use of collapse therapy in the presence of bronchial obstruction is less likely to be followed by complete clinical results than in the patient without this complication. Its use, however, is still justified, even in the presence of known partial obstruction with the knowledge and understanding, however, that complications may result and that subsequent secondary intervention may be necessary.

From the standpoint of treatment, this condition presents some points which are distinctly different from the treatment of bronchiectasis without associated tuberculosis. In the first place, bronchoscopic dilatation of stricture is less likely to succeed in these individuals than in non-tuberculous types. The traumatization of tuberculous granulation tissue is quite frequently followed by an increase in obstruction rather than a lessening of it. The surgical treatment of this problem must also be undertaken in a little different way. Pulmonary tuberculosis is a disease which is rather easily disseminated and contralateral spread of the disease or extension to an adjacent lobe is more likely to occur in tuberculosis than in non-tuberculous disease. The occurrence of tuberculosis in the wound is more likely to leave chronic discharging sinuses and persistent bronchial fistulæ than in the presence of non-tuberculous involvement. In spite of these points, we have been and will continue to be forced to attempt to do something for individuals with tuberculosis who present this distressing complication.

If the patient has obstruction which is nearly complete with retention of secretion and secondary sepsis and is desperately ill, some type of drainage operation may be more suitable than an attempt to excise the involved area. In this type of patient, either without or with thoracoplasty in the presence of obliterated pleural cavity, we have purposely chosen to use the Graham cautery type of external drainage and have had a few rather encouraging results therefrom. In spite of a number of disadvantages of this type of treatment, I believe that for individuals of this type it has advantages which outweigh the known disadvantages. For the patient who already has collapse therapy with obliteration of the pleural cavity and a lower lobe bronchiectasis without sepsis, primary lobectomy with excision of the involved lobe would be a nicer procedure. The dangers of over-expansion of an upper lobe diseased with tuberculosis in order to fill the whole pleural cavity with it to obliterate the space left by lobectomy cannot be disregarded, for the danger of re-activation of the tuberculosis present is certainly far from small. The danger of dissemination of tuberculosis to the contralateral lung, or generally, cannot be overlooked. The same points must be considered in total pneumonectomy for the complications of tuberculosis. A few such cases have been successfully treated by primary lobectomy or pneumonectomy, but fatal results have occurred in others and probably will continue to occur from time to time because of the very nature of the disease itself. However, in the tuberculous individual the complications produced by the late development of bronchial stenosis may be very distressing or disabling and may amply justify the risk entailed in attempting to relieve the patient of such a condition. The field is new and deserves much careful study and thought.

RECENT ADVANCES IN THE TREATMENT OF NEUROPSYCHIATRIC DISORDERS*

E. M. HAMMES, M.D.
Professor of Neurology and Psychiatry
Medical School, University of Minnesota
Saint Paul, Minnesota

DURING the past decade remarkable progress has been made in the various fields of neuropsychiatry. Recent studies in physiology, biochemistry, and electro-encephalography have enabled us to obtain a clearer understanding of the functions, the chemical structure, and the electric potentials of the central nervous system. The autonomic nervous system has finally been investigated to the extent that its importance to the vascular, glandular, and other systems is fully appreciated. However, further investigations are needed in this most interesting field.

The diagnoses of the various neuropsychiatric disorders have been placed on a higher and more scientific plane than ever before, primarily due to a more universal application of spinal fluid studies, due to a better understanding of the various neuropsychiatric syndromes associated with endocrine dysfunction, and especially due to a more thorough training in every field of medicine.

Neuropsychiatric therapy is keeping abreast with this diagnostic progress. Formerly our therapeutic armamentarium consisted almost solely in the use of sedatives, arsenic, electricity, and the more obvious surgical procedures. So many remarkable and almost specific therapeutic measures have been developed during the past decade that it is impossible to detail them in this brief summary. For that reason, only a few that are of general interest will be discussed.

The advances made in the field of neurosurgery, in intracranial and spinal neoplasms, in operations on the sympathetic nervous system, and in the treatment of cerebral injuries must be mentioned in passing. The progress in the past decade in this particular specialty, as to scientific ingenuity and as to therapeutic results surpasses every other surgical field.

Treatment of Deficiency Diseases.—The importance of certain vitamin deficiencies as etiologic factors in the development of various nervous diseases has been emphasized in the past few years and experimental studies have conclusively proven this relationship. Wortis has called attention to the importance of the enzymes and vitamins in brain tissue and believes that all central nervous and mental manifestations must ultimately depend upon biochemical reactions underlying brain metabolic functioning.

The principal vitamins which play a rôle in nervous diseases are: (1) the lipid-soluble vitamin A, (2) the water-soluble vitamins B (B1 and B2); (3) the water-soluble vitamin C; (4) the lipid-soluble vitamin D; and (5) the lipid-soluble vitamin E.

Absence or deficiency of vitamin A leads to xerophthalmia, deficiency of lacrymal and salivary secretion and at times to partial night blindness. Hughes, Lienhardt and Aubel fed pigs and chickens on a vitamin A deficiency diet. These animals developed impaired vision, muscular spasms and incoördination of movements. Degenerative changes in the long fibres of the spinal cord, in the optic, sciatic and femoral nerves could be demonstrated.

Deficiency in vitamin B1 produces polyneuritis and that due to vitamin B2 produces pellagra not infrequently associated with a psychosis. Prichart has further demonstrated degenerative lesions in the central nervous system caused by vitamin B1 deficiency.

Alcoholic polyneuritis is evidently due to a B1 avitaminosis and not produced by the toxic effect of the alcohol. The alcoholic has usually impaired appetite and digestion resulting in a reduced vitamin B intake. Jolliffe and his coworkers made a survey of the diet of twenty-six alcoholics with neuritis and sixteen alcoholics without neuritis. In every instance of the twenty-six alcoholics with neuritis they found an inadequate vitamin B intake. The sixteen alcoholics without neuritis had an adequate consumption of the vitamin based on Cogswell's formula.

---

*Read at the annual meeting of the Northern Minnesota Medical Association, Crookston, Minnesota, August 29-30, 1938, and The Minnesota Academy of Medicine, December 14, 1938.

Other studies by Wortis indicate that chronic alcoholics with polyneuritis or the various forms of alcoholic psychosis tend to have a subnormal vitamin C content of the blood and spinal fluid. This again emphasizes the nutritional factor in the production of nervous and mental changes in chronic alcoholics. Unfortunately the alcoholic psychoses do not respond as favorably to vitamin B therapy as polyneuritis does.

Zimmerman and his co-workers studied twenty-seven dogs who were fed on a normal diet except that it was entirely lacking in vitamin B2. The dogs developed a slowly progressive muscular weakness with incoördination, decrease of the deep reflexes, vomiting and bloody diarrhea, with death after three and a half to twenty months. The lesions consisted of marked demyelinization of the peripheral nerves and degeneration of the medullary sheaths and axis cylinders of the posterior columns. These pathologic changes were similar to those observed in cases of human pellagra.

Deficiency of vitamin C leads to scurvy and in advanced cases may cause headache, convulsions and delirium. These latter symptoms may be due to cellular anoxemic defects.

Vitamin D deficiency produces rickets. In some of these children the blood shows a low plasma calcium with normal inorganic phosphates, with a tendency to develop tetany.

Although vitamin E deficiency primarily produces sterility in both males and females, Evans and Burr have shown that a large percentage of the suckling young born from mothers deprived of vitamin E will develop a peculiar paralysis.

This brief summary emphasizes the important rôle of avitaminosis to neurological diseases.

The treatment of these disorders depends primarily in supplying the deficient vitamins either by a diet rich in these vitamins or in concentrated form in the various pharmaceutical preparations. Reference should also be made to the excellent results obtained with nicotinic acid in addition to a rich vitamin diet in the treatment of pellagra with prompt relief of the cutaneous lesions and also of the psychotic manifestations. Spies and his co-workers have recently reported a very interesting study of seventy-three cases with this disease treated with nicotinic acid.

Pfaffenberg and Mielke have also reported some favorable results in the treatment of early cases of funicular spinal diseases with vitamin B1.

Hirata and Suzuki treated 10 patients with progressive muscular dystrophy with large doses of vitamin C. They believe that vitamin C reestablishes the dynamic activity of the muscles and has a favorable influence on muscle metabolism. Their results are somewhat encouraging in the early cases.

Treatment of Infections.—Although intensive studies of the virus infections of the central nervous system have been conducted, no definite results have been obtained in many infections either from the etiologic or therapeutic standpoint. The organisms for poliomyelitis, encephalitis or herpes are still undetermined. Prophylactic and immunizing measures such as the nasal application of chemical compounds or the convalescent serum against poliomyelitis have not proven as successful as anticipated. Pette and Hampel have shown that the intramuscular injection of convalescent polio serum did not protect or alter the course of the disease in monkeys against polio virus inoculated intracerebrally. With intraneural inoculations (sciatic nerve) the immunizing results were more successful in some instances. Jungeblut believes that vitamin C may play a neutralizing rôle in preventing infections of the central nervous system. Paralytic doses of poliomyelitis virus when mixed with small amounts of crystalline vitamin C were rendered non-infective when injected into monkeys intracerebrally.

Measures against epidemic encephalitis, the scourge of our present generation, have been just as discouraging. When we consider the thousands of cases that have occurred in Minnesota alone, we can appreciate its ravages throughout the civilized world. Salicylates or acroflavine intravenously with spinal drainage have given results in some of the acute cases. Benzedrine sulfate, stramonium and belladonna may relieve some of the distressing sequelæ. The Pasteur prophylaxis against rabies and the antitoxin against tetanus with their remarkable results offer some hope that scientists in the near future may develop similar measures against poliomyelitis and epidemic encephalitis. Definite progress has been made in the treatment of the various forms of meningitis. The introduction by Jochman in 1906 of a specific antiserum against meningococcus infection followed soon after by spinal drainage materially lessened the mortality rate. Meningococcus antitoxin was developed by Ferry in 1932. Hoyne reported a mortality rate of 23.5 per cent in eighty-five cases with antitoxin as compared with 45.9 per cent in 211 cases with the standard serum. Other workers have reported similar results. With the introduction of sulfanilamide in 1935 and with this additional therapeutic measure the mortality rate has been further reduced, according to some writers as low as 9 per cent. Antimeningoccic serum or antitoxin intravenously with prontosil intramuscularly or sulfanilamide orally offers the best therapeutic results. Although the administration of this serum or antitoxin by the intraspinous route is being gradually abandoned because of the irritative effect on the inflamed meninges, repeated spinal drainage will favorably influence the course of the disease.

Other pyogenic infections such as streptococcus and pneumococcus meningitis respond satisfactorily in many cases to sulfanilamide. The virus infections, however, are resistant to this treatment.

Hemophilus influenzal meningitis (Pfeiffer's bacillus) occurs usually in children between the ages of two months and three years, with a mortality rate of 98 per cent. Fothergill has found this type nearly twice as frequent as the meningococcic type. A specific antiserum has been produced by the Massachusetts Department of Public Health. With this antiserum given intravenously and intraspinally the mortality rate has been lowered to 84.6 per cent.

The treatment of syphilis and of its involvement of the central nervous system is familiar to all. With the introduction of salvarsan by Ehrlich in 1910, the therapy of syphilis was placed on a rational basis and the tendency for involvement of the nervous system greatly lessened. In the treatment of parenchymatous syphilis, the various forms of salvarsan were largely replaced by tryparsamide prepared by Jacobs and Heidelberger in 1917. The Swift-Ellis and other forms of intraspinal salvarsan therapy are still utilized but their application is limited. The various forms of fever therapy, particularly the inoculation with malaria in general paresis, have materially increased our therapeutic results. Epstein observed that the percentage and duration of the remissions in general paresis are greater both clinically and serologically with malaria than with fever produced by diathermy and related mechanical modes of hyperpyrexia.

Within recent years, bismuth has gradually replaced the other heavy metals such as mercury. A very encouraging report has recently been published by Moore on the results of the treatment of syphilitic primary optic atrophy with malaria and the Swift-Ellis technic.

Marked progress indeed has been made in the prevention, in the treatment, and even in the cure of this disabling infection of the central nervous system.

Treatment of Convulsions.—The pioneer work of Berger in developing the electro-encephalograph and the resultant studies in normal and abnormal electric activities of the cerebral cortex have completely altered our viewpoint in relation to epilepsy. We now know that epilepsy is due to the development of abnormal rhythms in the cerebral cortex. Gibbs and Lennox classify epilepsy as a paroxysmal dysrhythmia. This abnormal rhythm obtained during seizures is distinctive for the three main types of epilepsy. The grand mal type has a fast, the psychomotor equivalent a slow, and the petit mal type an alternating fast and slow rythm. Because anticonvulsant drugs slow cortical rhythms, they are more effective in the grand mal than in other types of seizures. Clinical results have amply verified this effect on the grand mal type without any previous logical explanation.

Bromides have been used in the treatment of epilepsy for almost a century and are still recognized as a moderately successful anticonvulsant. This treatment has been gradually replaced by phenobarbital, first recommended by Hauptman. Phenobarbital is more effective, its prolonged use even in fairly large doses is not accompanied by mental sluggishness, acne or any of the other complications which may develop with continued bromide medication. The addition of the ketogenic diet suggested by Wilder in 1921 has been found quite valuable, particularly in petit mal in children.

Merritt and Putnam have been experimenting on cats with a new series of anticonvulsant drugs. Interrupted electric currents were passed through the animal's head and the effect of the drugs was determined by measuring the convulsive threshold.

Five drugs not previously used as anticonvulsants (diphenylhydantoin, acetophenone, acetophenone-oxine, benzophenone and propriophenone) were found to have a greater anticonvulsant effect than phenobarbital or bromides. These new preparations are being used clinically but no published results are available at present.

Although cerebral surgery has not been very successful in epilepsy, the excellent results obtained by Penfield in some of his carefully selected cases offer a more optimistic outlook.

Hyperpyrexia or Fever Therapy.—For many years clinicians have observed the favorable effect on chronic nervous and mental disorders when complicated by an acute infection associated with high temperatures and leukocytosis. The malarial treatment of paresis instituted by Wagner von Jauregg in 1918, however, was the first outstanding example of the clinical utilization of fever. Since then many methods have been employed. The intravenous injection of triple typhoid vaccine, diathermy, and other mechanical devices are the most frequently used.

The physiological phenomena observed in fever and their therapeutic role are as yet little understood. Studies suggest that fever inhibits the development and growth of invading organisms, that it has a stimulating effect on the functions of the hematopoietic tissues and a mobilization of reserve leukocytes, and that it produces significant changes in the functioning of the autonomic nervous system.

Among the neurological disorders, acute chorea has responded most favorably to hyperpyrexia. With intravenous injections of triple typhoid vaccines, the duration of the disease has been greatly shortened and the usual complications lessened in many instances. Electrically induced temperatures produce similarly favorable results. This therapeutic measure has also been found beneficial in multiple sclerosis by producing more frequent and more prolonged remissions. Since multiple sclerosis consistently tends to have spontaneous remissions, any form of therapy must be carefully evaluated. Everyone is familiar with the excellent results obtained with malaria in paresis. However, other psychoses, particularly the resistant melancholias, respond favorably to induced hyperpyrexia. Frequently one observes a decrease in the depression and a better insight on the day following a satisfactory temperature reaction.

Other Neurological Disorders.—In 1934 a committee was appointed by the American Neurological Association to study the problem of therapy in *multiple sclerosis* for a period of five years. Various types of treatment were suggested and are being carried out. Among these are the use of quinine hydrochloride, typhoid vaccine, malaria, silver salvarsan, intraspinal lecithin, high vitamin diet, viosterol, and liver. In our personal experience quinine hydrochloride orally with typhoid vaccine intravenously has been fairly successful.

The use of ergotamine tartrate for the relief of individual attacks of *migraine* has produced surprising results. Ergonovine, a similar drug, although not quite as active, has certain advantages. It is more readily absorbed by the gastrointestinal tract and for that reason more effective when administered orally. Nausea, evidences of uterine cramps and muscle soreness are less pronounced. In a series of 140 cases Lennox obtained complete relief from the attacks of migraine headache in 89 per cent with the injection of ergotamine tartrate. In seventy-eight patients, thirty-seven per cent obtained relief with ergonovine hypodermically. In cases where the headache is persistent, an additional intravenous injection of 2 c.c. of the amidopyrine compound, cibalgine, may terminate the attack. In all probability these favorable results from the ergot extracts are due to the contraction of the intracranial arteries and the depression of the heart rate. In cases resistant to this treatment, surgical procedures have been employed. Cervical sympathectomy, alcohol injection of the gasserion ganglion, section of the temporal artery or section of the meningeal artery have been followed by permanent relief in some instances.

Treatment of Meniere's Syndrome.—Although Meniere's disease is not fatal, the recurrent attacks of profound vertigo and falling may eventually lead to chronic invalidism, because of the tendency to recur. The medical treatment by Fürstenberg has given complete relief in many cases if carried out conscientiously and over a prolonged period. It consists mainly in an absolute sodium-chloride-free selected diet with large doses of ammonium chloride in capsules and some mild sedative. The surgical section of the auditory nerve has also proven successful in many stubborn cases.

Myotonia congenita with its inability to contract and relax voluntarily musculature has been greatly benefited by the use of quinine hydrochloride as suggested by Kennedy and Wolf.

The marked muscle fatigability due to *myasthenia gravis* has been relieved and the tendency to remissions increased by the administration of prostigmine and glycin.

The treatment of *narcolepsy* with benzedrine sulfate has given satisfactory results in relieving the attacks of uncontrollable sleep, if given in sufficiently large doses. This drug has also been recommended in the treatment of chronic encephalitis, asthenia, mild melancholia, and other forms of mental depression. However, its indiscriminate use should be discouraged.

Surgical measures have finally been devised for the relief of pain in many of the chronic neurological disorders. Morphine and its allied drugs, pantopon and dilaudid, are still our most powerful agents. However, the danger of drug addiction from pantopon and dilaudid, as well as morphine, limits their application in these prolonged or recurrent diseases associated with pain. The local alcohol injection or the radical cure by sensory root resection in trifacial neuralgia has given relief to many intense sufferers. Similar results have been obtained in other prolonged neuralgias by the intraspinal section of the posterior roots. The surgical removal of a protruded intravertebral disc has alleviated many cases of sciatica and its allied symptoms.

The epidural or subarachnoid injection of absolute alcohol for the relief of pain in metastatic involvement of the nerve plexuses or the spinal cord is a simple and quite effective procedure. In some cases, however, section of the pathways for pain in the spinal cord as suggested by Spiller must be resorted to.

The Treatment of Schizophrenia.—The medical literature as well as the lay magazines have been teeming with articles on Sakel's insulin hypoglycemic treatment and also on Meduna's metrazol convulsive treatment for schizophrenia. For that reason only a brief résumé of these two interesting therapeutic procedures will be detailed. Sakel's first publication appeared in November, 1934. The treatment consists in daily increasing doses of insulin, until the so-called shock dose is reached. In our personal experience this shock dose varied from 50 to 220 units. The insulin injection is always given fasting, the shock or unconscious period maintained for from one to two hours followed by a feeding of sufficient amount of carbohydrates, preferably about 200 grams of glucose by nasal tube. Usually six shocks are given each week with one day rest period. These shocks are repeated until the desired result is obtained. If no favorable results are obtained with forty to fifty shocks, the treatment should be discontinued. According to Potzl and Forstig, the symptoms of insulin shock may be divided into four groups:

1. The first group includes symptoms arising from the autonomic system—variation of pulse rate and blood pressure, drop in temperature, perspiration and salivation, pallor and flushing. Of these, the drop in temperature and the perspiration are the most constant and therefore the best indication of shock.
2. The motor symptoms start with restlessness and tremor, passing through various stages of twitching until pathologic reflexes appear. At the end there may be convulsions ending in muscular flaccidity and coma with areflexia.
3. The disturbances of consciousness start with sleepiness; then comes sleep from which the patient can be aroused; later he cannot be aroused and is in coma.
4. The mental syndrome is variable—the excited patient may become composed, or the stuporous patient may go into a state of extreme excitement.

The indications for terminating the treatment are deep coma with flaccidity, laryngospasm, generalized extensor rigidity of the muscles or severe convulsions, tachycardia, Cheyne-Stokes respiration or a sudden fall in blood pressure late in coma. In about 7 per cent of the cases of shock, early termination is necessary for one of these reasons.

Judging from the literature, approximately 50 per cent obtain a satisfactory remission. Death occurs in from 1 to 2 per cent during the hypoglycemic treatment. Intracerebral hemorrhage and widespread degeneration of the nerve cells in the cerebral cortex have been found at post-mortem.

Meduna's first publication on the convulsion therapy with metrazol for schizophrenia appeared in 1935. His method consists in administering intravenously a solution of 10 per cent metrazol daily in increasing doses until the convulsive dose is obtained. This usually averages between 7 and 10 c.c. The required dose to produce a convulsion is given from two to three times a week. The results obtained from this treatment compare favorably with those from insulin shocks. Although the mortality rate is materially less, accidents have occurred, the most frequent being a dislocation of the jaw or a fracture of the humerus or femur during the severe convulsive seizure.

Prolonged observation and future studies will determine whether these remissions will result in permanent cures.

In this brief review, many other recent and valuable therapeutic measures have not been referred to. When the etiologic factors in some of our chronic neurological diseases will finally be determined, we will probably be able to check the degenerative processes early in many of these cases and prevent a life of invalidism.

The results with insulin and metrazol in schizophrenia suggesting some biochemical reaction in the central nervous system, are stimulating renewed interest in research in the so-called somatic psychoses. Thus we may ultimately be able to determine some organic bases for these so-called functional psychoses and arrive at a better and more scientific therapeutic approach.

THE NERVOUS PATIENT*

A. E. MEINERT, M.D.
Winona, Minnesota

THIS evening I wish to say a few words about the nervous patient—the neurotic, if you care to call him that. In my experience, I should say the average practitioner gives too little attention to this patient, even though a fair percentage of his clientele consists of such people. As nervous patients, I wish to discuss not only the outright neurotic, such as the hysterical and the neurasthenic type, but also those who are nervously exhausted; patients who are too introspective, those with organic trouble who have a tendency to be neurotic and the individuals with vague complaints who fit into no clinical picture.

The more efficiently we treat this group, the better for the patients and the better for the profession. Many of the people who find fault with medicine come from this nervous group. Every physician gains a great satisfaction when he brings one of these patients back to normal health. Looking at the problem in this light makes it worth while for one to take greater care with each one. There is no question that the irregular healers derive a good share of their business from this large nervous group; and that gives us another reason why we should be more efficient in handling these patients. It gives us another means of decreasing the influence of the quacks.

---

*Presented before the Southern Minnesota Medical Association, Rochester, Minn., September 29, 1938.

Even though one does not particularly like this class of patients, one is bound to have considerable dealing with them. Through an understanding of the problem one will be aided in handling his organic cases as well. It is largely a problem of understanding human nature—and as physicians that should be one of our chief qualifications.

If you do not care to handle the outright neurotic patient, or if he gets on your nerves, you should refer him to one of your fellow practitioners. This will be better for the patient as well as for you. The so-called fixed neurotic should be referred to a psychiatrist who is better qualified than any of us to solve the problems which are in the background. However, the majority of nervous patients can be handled properly through the office or home by everyone of us.

I believe that we can all handle these cases better than we do, if we have the proper attitude—if we are sympathetic and try to understand the situation that they are in. We must first and above all gain their confidences. The fact that they come to us means that they have some faith in us or that they are going to give us a trial, at least. We will gain the patient's confidence by giving him sufficient time to tell his story—we should not rush him. By being interested, tactful, sympathetic and kind, we strengthen that confidence. We must realize that his symptoms are real, and that he is suffering, and is not coming to our office just to throw his money away, or to have a look at us. Each and everyone of us could develop a nervous breakdown, if the proper circumstances were put into our path. So let us be sympathetic with these people—they are not malingers.

Of course, in addition to personal experiences, heredity and environment are in the background in the more marked cases. Fear, worry, maladjustment, fatigue, and insomnia are some of the chief difficulties you must aid the neurotic to overcome. Their fears may be in regard to their health—they fear cancer, syphilis, heart trouble, or one of a thousand things. And, of course, there is always the fear of financial trouble or the daily problems of life to be considered. They will not always tell you that they are afraid of this or that, but you can learn to read their minds, or interpret this from the story they tell you. Fatigability, that is, always being too tired, is a most common complaint. Many of these individuals take on more activity than they can handle; and they must be educated to know their limitations and to stay within their nervous reserve. The systems to which most of their complaints are referred are the heart, the digestive system and the head. However, they are apt to have symptoms referred to various parts of the body at different times. In one consultation you may clear up their symptoms in one system, and the next time they may be back with a new set of symptoms involving some other part of the body.

As history taking is very important in all medicine, so is it especially important with neurotics. One can frequently suspect that a patient is neurotic from the way he enters the office. In others, the pad of paper with a list of complaints is suggestive. As I previously have stated, these patients should be allowed to tell their story, because you antagonize them if you rush them. By listening carefully, you will know what to rule out in the examination and also get an insight into their fears. If you let them talk long enough, they will drop hints in this regard. You will do a certain amount of questioning before you start your examination, just as you do with other patients. By the time you are ready for the physical examination, you have, in many cases, made the diagnosis of a neurosis. However, one must not be too cocksure and forget the examination. The writing of a prescription and dismissing of a patient at this time is what sends so many of them to quacks. It is most important that you give the patient no idea of your diagnosis by word or by action, or attitude at this time.

After being a good listener and showing the patient that you are interested in his problems, you will give him a thorough check-over. Many cases of incipient tuberculosis, syphilis, hypo- and hyper-thyroidism, focal infections, deficiency diseases and others are frequently difficult to distinguish from functional disturbances, if not thoroughly studied and thought out. So the first thing a physical examination will do for you is to aid you in making a correct diagnosis. The physical examination and history will suggest certain laboratory aids and these should not be neglected. Every patient should have a complete urinalysis, a complete blood examination including a differential count and smear study and a blood Wassermann test. Some patients will need a basal metabolic rate determination; some a chest ray; others complete gastro-intestinal studies such as gastric analysis, stool and proctoscopic examinations, and x-rays of the colon, stomach and gallbladder.

The second thing the thorough physical examination will do for you is this—it will give you the information that will allow you to be positive. When you tell your patient there is no organic trouble, you will be able to tell him this with conviction; and the patient will sense this. The reason the quack has a good hold on his patients is because he is positive of what is wrong with them and he guarantees a cure. We can be positive on a sound foundation and must learn to be convincing, and, through our attitude and assurance, we can get the same effect the quack gets through his guarantee.

The third thing that the complete examination does for us is this—it saves us time in the end. These patients are apt to return frequently, each time with a new set of symptoms. You can again listen carefully and then check him quickly. If no organic trouble is found you will explain simply what has brought about these symptoms and then give him plenty of reassurance. In the large majority of cases, this is what he wants to hear. He wants to be assured that nothing new has developed. This consultation will not be so time-consuming as the first one was. If, on the other hand, you haven't been thorough in your first examination, these patients may soon make you doubt your diagnosis in their frequent sojourns to your office. Your doubts will be read by the patient, and they will soon be going to another physician.

Of course, we must keep in mind that even a neurotic may in time develop a cancer, a stomach ulcer, or any other serious sickness; and so we must be constantly on guard with these patients in order that we do not slip up on our diagnosis.

In the treatment, may I repeat, the greatest good is accomplished through a careful history and a thorough examination. One is certain to have the patient's confidence when this is done, and when one has that, 75 per cent of the battle is won. However, in addition to being thorough and interested in the patient's problems, one should strive to develop a likeable personality. A smile, a word of cheer, optimism and kindness should be a part of every physician's armamentarium. These little things frequently help the sick much more than medicine. Why does anyone ever neglect them? Patients do not like the sober-faced physician, even though he is capable. One must also remember that no patient likes the rough physician whether that roughness be physical or mental. Sarcasm has no place in the practice of medicine, and I know of no quicker way to lose a patient than through this means. Many of our nervous patients leave the office cured after we tell them they have no organic disease, or if we specify that they have a normal heart or that there is no evidence of cancer or that no operation is necessary. With some, you will explain in simple terms how their symptoms are brought about. In many of these patients, the nervous reserve is low, and you need to explain that they must avoid taking on too many responsibilities and too many outside activities. You can explain how nerve cells in various parts of the body may fatigue and cry out for rest through the symptoms the patient has. Explain to them how rest, relaxation, and good nourishing food will restore vitality to these run-down cells so that their tiredness, their tight feelings and other symptoms will gradually disappear. Each case is an individual problem; but most patients will be able to grasp simple explanations if they are given them, and their recovery will be all the speedier.

Insomnia must be combated in some of these patients. Giving mild sedatives for several nights will break the habit with some. Others may be benefited by warm baths; and still others by being convinced that sleep is not essential in their particular case. If they can learn to relax and not fret or worry about their inability to sleep, many of them will fall asleep without outside aid.

Some nervous patients are benefited by a course of massage, or ultra violet ray treatment. Some of this therapy may be psychic, but it brings the patient back to your office frequently; and you have a chance to chat with him and bolster his spirits. Some people have a natural leaning toward chiropractors or osteopaths; and a course of physical therapy plus explanations of how their symptoms are brought about will assist them back to health.

One may need to resort to some symptomatic medication, but this therapy should be minimized and discontinued as soon as possible. Greater good is accomplished by putting emphasis on simple explanations and through assurances.

The diet may need to be regulated at first—using small meals five to six times daily. The diet should be of the smooth high caloric type at first and gradually the rougher foods can be added.

In our diagnosis we must not label these people neurotics. Instead, we should call their ailment nervous exhaustion, or a *touch* of a nervous breakdown, or a functional disorder. We should get the thought across to them that we realize that their symptoms are real and not imaginary. We should not tell a person "There is nothing wrong with you, it is all in your head." Such a statement is very tactless; it does no good and antagonizes the patient.

Each one of us has his own way of handling these cases. Your method is best for you, yet, I hope that some of the points I have tried to bring out will be of benefit to you. My plea is that we all take a greater interest in these unfortunates.

SOME POINTS ON CROSS-EYES*

JOSEPH B. GAIDA, M.D.

St. Cloud, Minnesota

WHEN the retinal image of an object is focused exactly on the fovea, the eye is said to "fix" the object. Normally, when both eyes "fix" the object, each eye has an image of the object on its fovea, and these foveal impressions are transmitted to the brain and fused as one image in the visual centers. This condition is spoken of as equipoise, or orthophoria, and the eyes are said to be in equilibrium or to balance. This is the normal eye. In heterophoria whenever one eye alone fixes an object, and the fellow eye receives the image of the same object on a part of its retina distant from the fovea, then the brain takes note of two separate impressions. This results in double vision or diplopia and the eyes are crossed, but can be put in balance by muscular effort.

Strabismus, also called heterotropia, "cross-eye," "squint" or manifest squint, is a condition of the eyes in which the amount of squint is so great that it cannot be overcome by muscular effort. It is a condition in which the visual axis of one eye is deviated from the point of fixation. The eye which has the image of the object on its fovea is termed the fixing eye, while the other eye is termed the squinting or deviating eye.

Except in paralytic strabismus, or heterophoria and heterotropia due to accidental injuries, one does not find diplopia in cross-eyed cases, because the patient from infancy automatically suppresses this duplicate perception. This is why, when one examines a cross-eyed patient, one finds, in nearly all divergent and convergent squints, a fairly good vision in the one eye and an amblyopia exanopsia (loss of vision due to disuse) in the other. Some ophthalmologists, however, claim that the amblyopia is a congenital defect which precedes and causes the squint. Ophthalmoscopically, these amblyopic or so-called "neglected" eyes may be entirely normal.

There are several varieties of strabismus. Esotropia or convergent squint, also called internal squint, is the condition in which the visual axis of one eye is deviated inward, the other fixing the object. This is the most common form of squint. Generally, both eyes have some form of hyperopia or farsightedness, usually a high amount, and as a rule the squinting eye is the more ametropic. A concomitant squint is characterized by the power of the squinting eye to follow the movements of the other eye in all directions, the angle of squint always maintaining the same size or degree.

---

*Read at the joint meeting of the Stearns-Benton and Upper Mississippi Medical Societies, Little Falls, Minnesota, October 22, 1938.

The angle of squint can be measured accurately by several special methods. A rough estimate of the number of degrees of strabismus can be obtained by watching the light reflex on the cornea of the two eyes, and measuring with a millimeter rule the amount of turning in or turning out of the eyes. For instance, if one finds that the left eye is turned in three millimeters, then one has approximately 15 degrees of left internal squint, as one millimeter of deviation represents five degrees of squint.

It is important to notice which eye fixes in squint cases. If, under ordinary circumstances, the same eye always deviates when the other fixes, we have a monocular squint. If, however, either eye fixes readily, we have an alternating squint.

Squint can be periodic, namely the mother notices the squint only when the child is tired in the evening, or during an illneses. It may be constant. It is probable that originally the crossing is only periodic, but by daily constant usage of the eyes at close range with a great amount of farsightedness, which must be overcome by the child as he converges his eyes on the near objects, the suppression of the deviating image becomes confirmed, and the squint becomes continuous or constant.

Squint is often noticed in children in the first year of life. The average age, however, is three years. Squints occurring after five years are apt to be alternating, in which case excellent vision usually exists in each eye.

The following causes of strabismus are to be noted: (1) the disturbance of the relation between accommodation and convergence by errors of refraction; (2) the inequality in the vision of the two eyes, or amblyopia of one eye, which removes the natural stimulus of diplopia to exact convergence; and finally (3) disturbances of innervation and defective development of the fusion faculty. Defective innervation may affect the muscles and cause a shortening of the internal recti muscles, causing convergent squint, or relaxation of these same muscles may occur, which would cause divergence. The fusion center is in the cuneus, in the occipital lobe, and may suffer birth trauma. Sometimes, because of a congenital defect, the fusion faculty develops later than it should, or imperfectly, or not at all, in which case there is nothing to stimulate a coordination of the eyes, and, consequently, a permanent squint results. The fusion center is not fully developed until about the seventh year.

It is in these cases with poor fusion that one finds, besides the usual moderately high amount of ametropia, that certain eruptive fevers and infections, especially whooping cough, seem to bring on the squint. The severe illness or shock acts as a provocative agent in the presence of this fundamental cause of squint.

The influence of heredity is important. There is nearly always either a history of squint, left-handedness or stuttering, or all, in either the parents, parents' brothers and sisters, or paternal or maternal grand- or great-grandparents. Dr. Wenner and I have recently seen two families in which both of the parents were cross-eyed, one with seven children, the other with five, all of them cross-eyed.

Treatment of Convergent Strabismus

At the outset, it should be stated that no one, especially no doctor, is justified in advising a questioning mother or father to leave the squint alone, or, as it used to be said, "He'll outgrow it." Probably the eyes will become straight, a small percentage do, but blindness of the crossing eye is the price the patient has to pay. What if this person meets with an accident and loses his good eye? He then has only a blind or nearly blind eye, normal to all appearances but unable to perform its function.

In treating cross-eyes one must strive not only to correct the squint cosmetically, but also to improve or retain present vision. This can best be accomplished in children before the fifth year, and frequently up to the seventh, but only occasionally after that, because the fusion power is fully developed about the sixth or seventh year.

Treatment of strabismus will be discussed under three separate headings.

Refractive Treatment

Glasses which neutralize the refractive error should be ordered for every case of convergent strabismus. The refractive error must be accurately determined by retinoscopy after the use of atropine has thoroughly paralyzed the functions of the ciliary muscle. Atropine must be used for at least three days before retinoscopy is attempted. In the majority of cases the refraction is hyperopic, and is often associated with astigmatism.

Examine the eyes for strabismus while under a cycloplegic. Are the eyes parallel? Is the amount of strabismus as great as or less than before atropine was used? If you find the eyes parallel, you may be reasonably certain that the squint is very receptive to treatment, and the eyes will straighten out under the proper correction. If the squint is less than before the cycloplegic was used, it may be because of hypertrophy of the internal recti, and these eyes, too, in time, will straighten out under proper treatment. If the angle of strabismus is as great under atropine as before, the chances are that other additional methods besides glasses will be needed for correction.

After retinoscopy, prescribe the full amount of astigmatic correction with about a half diopter hyperopia less than the full amount found. Hitz[2] states, "The full correction of hyperopia in internal strabismus will often produce much greater reduction in the angle of strabismus than the correction in which one-half to three-quarters diopter is subtracted." It is preferable to subtract a half diopter, especially if the correction is the first one made, and later give a full correction if any squint still remains.

It is important that this non-operative treatment of squint should be begun as soon after the discovery of the condition as is possible, and glasses can usually be given a child as early as eighteen months. The youngest fitted in our practice was thirteen months, with a prompt correction of the squint.

The use of prisms ordinarily causes no improvement, and occasionally increases the amount of squint, as it weakens and reduces the effort to fuse.

Educational Treatment

Orthoptic training by the use of some type of stereoscope is very helpful to stimulate fusion, as this breaks up suppression, establishes diplopia, true projection, and stimulates binocular vision and stereopsis. Low degrees of strabismus may be corrected by orthoptic training alone. Within recent years, many new types of mechanical and box stereoscopes have been placed on the market. All have their good points. In our office, the Wottring Rotoscope is used and a vertical diplopia is established. This method is more prone to succeed than when an establishment of a horizontal diplopia is attempted. Orthoptic training is very useful before surgery. After operation, patients who have parallel visual lines, good vision in both eyes and true projection may be left to their own urge for fusion to develop binocular vision. Patients with residual deviation and suppression should be given orthoptic training until they have binocular vision with and without glasses. Many cases of latent suppression that respond very nicely to orthoptic training are found even in cases without squint.

Occlusion of the fixing eye, that is, occlusion of the good eye by a shade or occluder, is resorted to immediately or soon after the refraction. The good eye is covered with the hope of increasing the visual acuity of the poor eye, as well as to compel the poor eye to use such vision as it has to promote fixation, and to stop the habit of suppression.

Instillation of atropine into the good eye to blur its vision is not as satisfactory as using the occluder, as the atropinized eye often sees better than the poor, unatropinized eye.

Bar reading, or controlled reading of Javal where a bar or strip is placed so that only part of the page is seen with either eye, has been supplanted by most of the stereoscopes. The Wottring Rotoscope uses the bar principle.

About five years ago, I had the privilege of working with Dr. Fink and Dr. Bryngelson[1] of Minneapolis in their original research on the relation of stuttering and left-handedness to cross-eyes. Here was used a type of treatment for cross-eyes that occasionally is effective. A thorough history of left-handedness and stuttering was obtained in all cross-eye cases. If a child were found to be cross-eyed, or was stuttering, investigation often showed that the child was originally left-handed, and that the parents had at some time previously insisted and forced the child to use his right hand. All these children were made to use their originally normal left hand. Occasionally, the right hand had to be tied, as they had become so proficient in its use, and in many cases, after variable lengths of time, the cross-eyes would begin to straighten out. Stuttering was also treated in this manner with other approved speech practice methods with good results.

Surgical Treatment

If the squint is of a high degree, 20 to 40 degrees or more, the treatments outlined heretofore are used, but, of necessity, there must be a mechanical and anatomic adjustment of the eyes, as it is impossible in some of these cases to turn the eye out far enough to hold the head straight. Operation must be resorted to in these cases, as well as in those that do not respond to the aforementioned treatment.

Operation is resorted to in these highly convergent squints to bring the eyes parallel, or nearly parallel, to aid the child in developing good vision, and at the same time to get a cosmetic result. In children of school age, it is not uncommon to hear them called "cock-eyed," and many other names, by their schoolmates. It is, therefore, also of psychological importance to correct cross-eyes by whatever means possible, as many of these children develop an inferiority complex if left alone. In older children and adults, surgery is purely for cosmetic reasons, as at that time it is impossible to develop fusion or to improve vision. Here, too, the cosmetic result is of great importance, especially in young women.

In children, operative treatment should not be undertaken until the refractive correction has been worn for at least six months, and the occluder and orthoptic treatments have been resorted to without results.

Types of Operations

No single strabismus operation should be used in all cases. In some, it is necessary to do a recession of the internal with an advancement or resection of the lateral rectus muscles. Occasionally, both eyes have to be operated upon before parallelism is obtained. The above surgical procedures may have to be repeated on the other eye, or a tenotomy and/or a tucking done on this eye at some future time. It is poor surgery to operate on both eyes at the same time. It is much better to over-correct than under-correct in convergent strabismus operations.

In divergent strabismus, one usually finds a myopic error of refraction. Here a full correction is immediately given with the idea of making the eye accommodate for near work, and by so doing build up a convergence power and straighten out the strabismus. A divergent squint, even of a small degree, is more noticeable than an internal one. Here, surgery must be resorted to more often and earlier, as in these cases we usually find a thin, weak internus muscle and tendon. This is advanced and occasionally one must do a recession of the externus muscle before parallelism is obtained.

In alternating strabismus with good vision in each eye, satisfactory results may follow careful tenotomy of the internal recti muscles. If a squint is still present, which cannot be controlled by glasses and exercise, and should there be a preference of the fixing eye with loss of vision in the other eye, as occasionally happens, the external rectus of the poorer eye may have to be advanced.

Irrespective of whether refractive, educational or surgical treatment is used, squint or cross-eyes should be subjected to continued care from as early a date as possible until satisfactory therapeutic results have been obtained. This is evidenced by a cosmetic result of parallelism of the visual axes, good vision, or a preservation or improvement of the vision in the squinting eye.

EXPERIENCES WITH SISTOSAN, A NON-IRRITATING HEMOSTATIC*

ARNOLD SCHWYZER, M.D.

Saint Paul, Minnesota

THE intention of this paper is to report our experience with a preparation made by Dr. L. Pancaro of Sudbury, Ontario. He calls it sistosan (a contraction of two Latin words, *sisto*—I arrest, and *sanguis*—blood). It is an extract from over a dozen plants and roots: Rosemary, Centaury, Nettle, Cochlearia, Mint, Root of Arnique, Root of Oak, Assent, Angelic Root, Elm Root, Marjoran, Ipericon, Matico, and Origan.

From the beginning it should be stated that the weak point in bringing this subject before you is the fact that even the maker of this preparation cannot furnish any chemical analysis of the active principle or principles. This would entail perhaps insurmountably difficult chemical study. We do not even know which of the plants work the most. In these days when one is swamped by proprietary medicines, one is ready to discard such remedies without further trial in as much as our Council of Pharmacy has not yet given its judgment of the remedy.

On the other hand (and this is the reason I bring this matter before you) I must say first, that this hemostatic has helped me out of tight places too often to make me refuse to acknowledge its effect and my gratitude; and second, I know Dr. Pancaro, a former interne at St. Joseph's Hospital, to be a thoroughly sincere student and an unusually well grounded physician. He has made a great many experiments with the substance to determine the mode of action which seems different from that of other preparations. He reaches the conclusion that it stimulates the leukocytes toward a prompt giving off of their profibrin ferment. The compilation of the extract of the different plants and roots he received from his father, also a physician, who as a good botanist had devoted many years of research to this subject. I can vouch for the integrity of Dr. Pancaro whose primary desire in developing this preparation was not commercialism but the intense desire to save life. In this condensed report we shall have to omit the history of the development of the product, which he prepared as an aseptic and even slightly antiseptic solution. It does not interfere with wound healing in the least as you will learn from the case reports. Given internally the coagulation time was somewhat reduced. Administered intravenously up to 10 c.c. per day to a dog weighing fifteen pounds no untoward symptoms appeared.

A demonstration before a medical group at Ottawa was particularly impressive. A medium sized dog's carotid and internal jugular were cut half way through and by application of sistosan on cotton under digital compression, the hemorrhage ceased so that after removal of the cotton, the wound could be closed by a simple skin suture. This appeared almost fantastic, so that I wanted to see it repeated. Dr. Warner F. Bowers, assisted by my son, H. C. Schwyzer, kindly did so in the laboratory of the Surgical Department of the University of Minnesota on February 29, 1936. The dog weighed 17 kilograms. The carotid was about the size of an ordinary lead pencil. Let me now quote the notes made by Dr. J. C. Klein and myself at the time of the operation.

> "595 mg. of nembutal intraperitoneally had been given for anesthesia. The common carotid on the left side was cut one cm. lengthwise and about one-fourth of the way crosswise, forming a cross incision. Cotton soaked with sistosan was applied and pressed on. After two minutes pressure was released. After five minutes the cotton pledgets were removed, and there was no trace of bleeding. The vessel can be handled with forceps and still does not bleed. The vessel was then cut completely across with very profuse bleeding. Sistosan applied. After two minutes of compression bleeding diminished, and after three minutes compression there was apparently no bleeding. After five minutes the pressure was almost released, after six minutes released completely. Ten minutes after sectioning the vessel, we start to remove the pack. After fifteen minutes, the innermost cotton pledgets are lifted, when bleeding starts again. Renewed application of sistosan on the innermost pledgets with compression for one and a half minutes. Thirty-one minutes after the carotid had been cut the last pledget is removed. There is no bleeding. Wound closed without any ligatures, some sistosan being left in the wound. For the two experiments 60 cc. of sistosan were used in all. A subcutaneous injection of two c.c. of sistosan was made laterally on the neck beyond the wound, for later examination."

---

*Condensed from a paper read before the Ramsey County Medical Society, Saint Paul, Minnesota, November 28, 1938.

On March 9, 1936, the dog which had appeared normal was killed.

> "Exploration of the wound showed some hemorrhage in the fascial planes of the neck extending to the larynx. The carotid artery was collapsed cephalad and did not contain a thrombus. There was no thrombosis of the caudad segment. Each cut end was surrounded by a firm coagulum to involve not more than 1 cm. of the vessel at the point of section. The point of subcutaneous injection was somewhat indurated. On opening the thorax, there was mediastinal hemorrhage down to the level of the heart, on both sides of the vertebral column. The subcutaneous tissues over the clavicles were also infiltrated with old blood."

Inasmuch as there was no hematoma present in the wound, the hemorrhagic infiltrations in the mediastinum were undoubtedly due to the manipulations of compression for hemostasis at the time of the operation and to absorption from the blood-imbibed wound.

After making this experiment I started to rely more on sistosan in my operative work, whenever it seemed advisable. Many times it was a great comfort to have an agent to combat diffuse troublesome oozing or free bleeding when access to the bleeding vessels was difficult or associated with danger. What struck me in clinical work as noteworthy was not only the promptness of clotting but the firmness of the coagulum and the dryness (comparatively speaking) of the blood-soaked gauze packs used for compression. Some of the colleagues to whom I have given sistosan have been much impressed by its value while others had had no real results. Those from whom I have received word will be mentioned in the report on the use of sistosan in different regions. If we consider that the substance acts simply in hastening coagulation and in rendering the clot more firm, it is readily comprehensible that in removing the gauze or cotton too soon, the clot which has become enmeshed in the gauze, is pulled out of the vessel and the bleeding recurs. At times we have found it of advantage in cases where bleeding recurred after removal of the gauze to exert a little pressure with a gloved finger moistened with sistosan or to make gauze compression on an interposed rubber dam.

The use of sistosan in a number of surgical cases will now be reported. I have used it personally over a hundred times. The cases will be arranged going down from the head to end at the extremities. All of my cases reported in this paper were operated upon at St. Joseph's Hospital.

Dr. R. T. Muller reports to me a case of an *endothelioma of the skull.* The growth, the size of a hen's egg, was exceedingly vascular. Bleeding was decidedly disquieting. Adrenalin and compression with very hot packs had hardly any effect, but after application of sistosan there was no bleeding when three minutes later compression was discontinued. Dr. Muller thinks the sistosan saved the patient.

Dr. Livingstone of Hudson, Wisconsin, used sistosan in a case of *persistent bleeding after a tooth extraction.* The bleeding stopped permanently after cotton soaked in sistosan was applied and the patient instructed to keep his jaws closed for half an hour.

Bleeding *after tonsillectomy* was successfully treated in over eighty cases as reported by Dr. Pancaro. It may be of value to apply first a thin pledget of cotton and bulkier ones over it. Then the innermost layer may be left for an indefinite time after removing the outer ones.

Dr. Sprafka of Saint Paul reported on a child eight years old. Hemorrhage from the wound occurred six days after tonsillectomy. Adrenalin and tannic acid checked the bleeding temporarily only. Sistosan applied with pressure for six minutes stopped bleeding permanently.

In a case of *parotid tumor,* sistosan combined with firm compressure for three minutes checked troublesome bleeding. Healing was perfect.

Carcinoma of submaxillary area.—This patient had a large metastatic carcinoma of the submaxillary area from a growth on his lip which had been treated by his home doctors with large doses of x-ray and radium since November 1935. He came to us in April 1937. The mass was removed *in toto* together with the overlying skin and the adjoining muscles, including portions of the sterno-mastoid muscle. Oozing was marked, though not excessive. Sistosan checked it effectively. Later a pedunculated flap was formed to cover the defect.

In *goiter work* there may be a rare instance where sistosan comes in handy. Dr. A. E. Naegeli of Saint Paul asked me for some sistosan when serious bleeding occurred in a thyroidectomy for a toxic goiter. The gland appears to have been very friable, sutures pulled through and tying was difficult. Pressure with ordinary gauze checked the hemorrhage only partly, but ten minutes after applying gauze soaked with sistosan the bleeding was controlled.

I have records of four personal cases of thyroidectomy where the lotion was used. In one of them for instance there was a bleeder on the right side of the trachea where fear of interference with the recurrent laryngeal nerve made us apply some sistosan. The bleeding stopped. Recovery was prompt.

Carcinoma of the thyroid gland.—Profuse free bleeding and oozing occurred on removal, July 13, 1937, of a right sided tumor which was firmly adherent to the surroundings. Sistosan checked the bleeding effectively.

Gastric bleeding.—Dr. Pancaro speaks of good effects from internal administration. In one of our cases of marked, though not severe bleeding after gastro-enterostomy, the vomiting stopped after administration of three tablespoonfuls, and the further course was smooth. How much of this was due to the sistosan remains questionable, but it shows that the stomach accepts sistosan without revolt. In two other cases (one of my own and one of Dr. Naegeli's) of profuse bleeding with no preceding operation, sistosan did not help. Local application and compression is here out of the question.*

Oozing from liver surface after cholecystectomy.—Of four such cases two could be closed tight. The other two had abscesses between the gallbladder and the liver and were therefore drained. Smooth recovery took place in all four.

Trauma, ruptured pancreas and mesenteric vessels.—Dr. Naegeli had a case of crushing injury to the abdomen caused by a one thousand pound weight. The hemorrhage was profuse retro-peritoneally and could not be checked by ordinary means. A gauze pack soaked in sistosan was used and the hemorrhage was controlled. At the autopsy three days later no hematoma was found. The bleeding had therefore been checked definitely.

A rapidly growing *sarcoma of the mesosigmoid* the size of a man's head was removed May 2, 1936. The bleeding was of course profuse. After removing the tumor as expeditiously as possible a gauze soaked in sistosan was introduced, and the parts compressed. After that the edges of the lateral leaf of the mesosigmoid were re-approximated by suture and the abdomen closed tight. Uninterrupted wound healing followed.

A patient with *intestinal obstruction* due to widespread *post-operative adhesions* involving almost the whole tract of the small intestine after operation elsewhere for an ovarian dermoid and reoperation for adhesions, came to us and was operated upon November 25, 1936. Small intestine loops were so firmly grown to the abdominal walls at the site of the former incisions that we barely missed opening the gut in several places. One loop had a fibrous attachment to the depth of the pelvis at the site of the stump of the ovary. The patient was so extremely emaciated and weakened that only the worst and obviously obstructing parts could be freed. We predicted that we might have to do more later on, as the omentum was not to be had for protection. Considerable sistosan was used on the oozing gut and some was left in the peritoneal cavity. Recovery was very prompt. Fifteen days after the operation she came to the office, and my associate made the entry that she had gained ten pounds since the operation. She felt pretty well for three months when in March unbearable cramps recurred and became so severe that she had to be reoperated on May 17, 1937. Since then she is reasonably well though she often has much pain. At our second operation, the fourth one for the patient, firm adhesions had been encountered at the abdominal walls and in the pelvis though not near as bad as at the first.

I am under the impression that sistosan does not make adhesions, on the contrary in checking the oozing, counteracts the formation of such. We have used it many times in pelvic work leaving 30 or 50 c.c. in the peritoneal cavity if it seemed desirable on account of much oozing, as in several advanced malignant tumors of the ovaries when the soft growth had broken through the surface and adhesions were present with many oozing areas. As a striking example let me report in short, one case. A Catholic Sister was operated upon on January 21, 1937, for a *sarcoma of the ovary* involving the tube. Her hemoglobin was only 50. It was decided to transfuse her not before but directly after the operation. The tumor, about the size of a six year old child's head, was adherent to loops of small intestine all over the sides and posterior circumference. We first freed one loop and the bleeding was excessive from the junction between mesentery and gut as well as from the tumor side. Compression by doubling up the gut on its mesentery only partly reduced the bleeding. It appeared that we should lose the patient unless we succeeded in freeing the mass quickly from all the loops of intestine (six or eight of them) and could then stop the bleeding. There was, of course, no time to be lost tending to individual bleeders. As rapidly and gently as possible we separated the tumor from the many loops. Sistosan was poured into the wound and while we proceeded, compression was made as well as possible. The pedicle was reached, clamped, and the tumor cut away. Now more effective compression of the mass of raw oozing guts could be accomplished with large sistosan-soaked packs. This controlled the bleeding reasonably well. The other ovary was then looked for. It was the size of a plum, white, and imbedded in adhesions. It was removed while compression of the guts was kept up. Another ounce of sistosan was poured into the pelvis and the abdomen closed. A transfusion of 660 c.c. of blood was then given, and the recovery was very good. Upon inquiry the patient wrote us April 10, 1938, that she had gained over forty pounds in weight and was feeling very well.

---

*Since reading this paper sistosan was given internally in a case of severe gastric bleeding. A tablespoonful was administered every hour for three doses and followed with a teaspoonful every two hours for twenty-four hours. The hemoglobin had come down from near normal to 35 per cent within two weeks, and the feces seemed to be almost all blood. After sistosan, the feces became free from blood. Resection of the stomach (Feb. 24, 1939) then demonstrated a malignant mass with a deep ulcer an inch in diameter.

It would be too tedious to report on all the abdominal cases where sistosan was used, such as complicated carcinoma of colon and rectum or extraperitoneally developed fibroids between the layers of the broad ligament, or severely adherent adnexa, and several broadly adherent malignant growths, etc. Among minor things, there were two cases of viciously prolonged bleeding from simple punctures of small ovarian cysts, where sistosan checked the annoying oozing.

In *nephrolithotomy* we have used sistosan five times. One patient, Mrs. J. S., was operated upon February 1, 1937. Three stones were removed by incising through the cortex of the kidney. Sistosan was applied to check the bleeding.

Another patient, Mr. H. G. E., operated upon December 1, 1936, had a large branched stone and some smaller ones. They were removed through a cortical incision, three inches in length. The bleeding was stopped partly by sistosan with compression, partly by suture.

A third case of renal calculi was Mr. C. W. M. On November 30, 1937, a nephrotomy was made which allowed us to deliver a calculus 3.5 cm. long and a smaller, hard, white one. The bleeding was severe as we did not clamp the hilum for fear of crushing the stone. Sistosan on a gauze sponge together with compression for several minutes checked the bleeding enough for a suture under vision.

A fourth patient was operated upon March 11, 1938. Mr. J. A., a strong man of forty-one years, had a complete obstruction from a stone at the uretero-pelvic junction. The temperature was 104 degrees and there was so much peripyelitis (the tissues being baked together at the hilum) that a moderate sized cortical incision was made through which some smaller concretions were first removed from the lower calix and then the conically shaped calculus from the pelvis. Due to the small size of the incision (about 4 cm.), the vessels could not be satisfactorily sutured in the depth, and the sistosan together with compression was used.

These four patients made good uninteruped recoveries following nephrotomy. In the meantime we had other nephrotomies where we did not have to use sistosan. But in this kind of operation one is especially glad to have an agent for controlling bleeding. Of particular interest was the fifth case.

This patient was operated upon very recently. Besides a large stone there were smaller ones up to the size of a french pea and in the lower calices much fine gravel. This case is of particular interest for the discussion of sistosan, as *in some other way* we made use of its quality of forming a firm coagulum. After the removal of the large stone through the open kidney and after the scooping out of the more sizable of the smaller calculi there was a great amount of gravel to be felt. The kidney pelvis readily filled with blood as an almost cartilaginous perinephritis and the fear of forcing the material into the ureter had made us desist from clamping or constricting the hilum. A sistosan-soaked gauze sponge was inserted into the kidney pelvis and left for a while. A firm clot formed in the calices and was, of course, more adherent to the gauze than to the smooth lining of the calices. When the gauze was removed a large number of small stones came away with it and after repeating the procedure once more, the finger could not detect any grit anywhere. The firmness of the clot formation and the non-irritating character of the sistosan were particularly helpful in this case.

Mrs. S. G. was operated on February 18, 1937 for a *solitary cyst of the kidney.* It was on the posterior surface, about midway between the two poles and was the size of a tangerine. It was cut out of the parenchyma, sistosan was applied and the kidney wound approximated by sutures. Recovery was prompt.

Suprapubic prostatectomy.—Even when there is very little bleeding after the enucleation of the prostate, we always compress the bed with a sistosan-soaked gauze or a piece of rubber dam after sistosan is poured into the bladder. Sistosan seemed very valuable in this work, but to say that it was the deciding reason for having lost only one case in our last forty-two suprapubic prostatectomies would not be correct as the large majority were before we had sistosan. Compared with other cases there was, however, less bleeding after the operation. Since we have used sistosan, the urine was as a rule macroscopically free from blood within one or two days. I will mention just one case where we removed the prostate suprapubically and at the same session excised a large *diverticulum of the bladder.* In 1933, a year before he came to us, a well known urologist had made a transurethral operation for prostatic obstruction, but when some difficulty arose, had to open the bladder suprapubically. A diverticulum of the bladder had been recognized before operation. The patient consulted us in March, 1937, and had much misery and urgency. There were 400 c.c. of very foul residual urine. After washings and silver nitrate treatments, the residual quantity was reduced to 275 c.c. and was of considerably improved quality. On March 13, 1937, we re-opened the bladder suprapubically and made an enucleation of the very hard prostate. Sistosan was applied and the bleeding was well stopped. Considering the number of operations the patient had had to go through, together with his mental and financial circumstances, we decided to remove the diverticulum at this same session, though it appeared difficult of access. It was almost directly back of the bladder, a little to the left side and the roentgenogram had shown it to be about four inches in height. The left bladder wall was freed. The left ureter ran over the side of the diverticulum and had to be dissected free. After the diverticulum was removed and its opening into the bladder closed, sistosan was poured into the bladder. Recovery was surprisingly prompt. I doubt whether I should have had the courage to have operated in one session without the help of sistosan.

Operations on the *extremities* where we used sistosan were only few in number.

A *varix aneurysmaticus* of the wrist in a boy of seven years was operated upon. Obliteration by suture was done but bleeding was not checked completely. Rather than do more suturing, sistosan was applied and after forty seconds there was no oozing even on straining. The wound healed promptly.

Dr. Pancaro reports good result in fifth day hemorrhage from wounds, in other words, in cases of a septic melting down of the primary thrombus in open wounds. In one such case we have to register a failure. A boy had received an injury to his wrist from an explosion of a shell. His doctor explored the wound for one and a half hours trying to find a piece of metal which the roentgen picture showed. The bleeding was so persistent that he finally had to quit and pack the wound. But alarming bleeding recurred repeatedly on successive days, and I was called in consultation. The curled up piece of shell was found directly over the carpal bones underneath the tendons. Sistosan was applied for a short time while the tourniquet was removed. There was no bleeding and the wound was partly closed. The patient left the hospital but was brought back in a hurry a week later on November 26, 1937. A renewed severe bleeding had occurred. After enlarging the wound and removing a hematoma the size of a chicken egg, the spurting ulnar artery was ligated and also another smaller one. Sistosan was applied and the wound partly closed. From then on the wound healing was smooth.

An *amputation above the knee* for *senile gangrene* did not need a single ligature, though for safety sake a fine catgut was placed around the thrombosed femoral vessels. The bleeding points were simply compressed for a few minutes by gauze soaked in sistosan. This controlled all bleeding. One might think that perhaps such a foreign substance would endanger the very poorly resistent tissues as a stump of amputation for senile gangrene. However the wound healing was perfect, and the lack of ligatures in the wound was a point in favor of such procedure.

That sistosan does not damage the tissues is best demonstrated by the good result we had in two cases of *skin transplantation.* They were for *varicose ulcers of the leg.* After excision of the ulcers and their thickened base, bleeding was not promptly stopped by ordinary compression. Sistosan was then used. The thin Thiersch flaps took perfectly.

So far we have not had any experience in cases of blood dyscrasias, a field which might yield valuable results inasmuch as Dr. Pancaro reports that he injected the fluid intravenously up to 10 c.c. per day into a dog of fifteen pounds, without untoward results.

Sistosan seems to have a good effect even if administered orally as in some cases of menorrhagia, but my intention was to bring before you only what I have observed myself. I am sure it has helped me out many times in dangerous conditions and very often brought at least a sense of greater security when extensive intraperitoneal oozing was disquieting. As it appears to me, the value of sistosan consists of causing the blood to clot more rapidly, and principally of an apparently better contraction of the clot as expressed in its dryness. The clot is more firm as demonstrated by the observation that the thrombus which blocks the cut vessels is not far progressing in the lumen, but nevertheless stops the bleeding effectively.

Some of my colleagues, it must be said in fairness, had no demonstrable results with sistosan, but I wonder if the time of compression was not perhaps too short or if it was not used where the remedy had no proper chance to come into contact with the vessels. I am inclined to say that in order to get results one must have the courage of the conviction that sistosan will work if it can be given a proper chance. Where clots hinder the remedy from reaching the vessel lumina we cannot expect much. Recently a case of severest nose bleed where the blood gushed forth like from a small aneurysm and the patient was brought to the hospital cold, clammy, and practically pulseless, neither sistosan nor "tuffon" in connection with firm packing of the nares from behind and in front after application of trichloracetic acid, controlled the bleeding more than temporarily. Ligation of the external carotid had to be resorted to.

Dr. Pancaro contends that results were observed in hemoptysis and in hematuria. As the *post hoc* is not necessarily a *propter hoc,* and as I have not had occasion to use sistosan in such cases, this is only mentioned in passing.

Several hemostatics are on the market. Already long ago Fonio, a former assistant of Kocher, made a preparation from blood platelets in powder form, and called it *coagulen.* It was of good help in some cases of mine and of several of my colleagues. It is applied in powder form. We did not feel safe to use larger quantities in the abdominal cavity.

A similar preparation in liquid form seems to be the recently advertised *"ercé,"* a lipo-colloid suspension of thrombin. It comes in ampoules of 5 or 20 c.c. Like Fonio's coagulen, this French preparation may be said to act physiologically in bringing to the fibrinogen in the blood, the agent—the thrombin—which causes coagulation under usual conditions. Ercé is claimed to coagulate blood in twenty sconds. I have had no experience with it.

Another preparation is *"tuffon,"* a German product which I saw used with prompt effect by Prof. Henschen of Basel in Switzerland this past summer. In one of our own cases bleeding from the bone marrow in an amputation of the leg was promptly checked. A firm rubbery mass promptly formed of blood and this coagulant, which contains among other things, tragacanth.

You heard recently of the vitamin K (Koagulations-vitamin) as opening possibilities in hemorrhagic diatheses. The experiments with several other preparations demonstrate the urgent desire for a reliable hemostatic.

Sistosan, in its liquid form, harmless even in large doses in the peritoneal cavity, has advantages of much merit. To claim too much for it would hurt its use. I would not trust too much any remedy in a treacherous case but one thing is sure: I should not like to be without this preparation. It has proved itself too often a good friend in need and I feel very grateful to Dr. Pancaro for this efficient and innocuous hemostatic.

HISTORY OF MEDICINE IN RAMSEY COUNTY

BY J. M. ARMSTRONG, M.D.

(Continued from March issue)

1865

A number of physicians came to Saint Paul in 1865 apparently to look over the prospects. Among them were Samuel D. Flagg and Albert E. Senkler. The former moved to Saint Paul permanently the following year, and the latter settled at Saint Cloud and moved to Saint Paul in 1880. Both became prominent in local and state medical affairs in later years. Of interest to residents of old Saint Paul was a petition made by Dr. Rosenk to the common council in March. He stated himself to be the owner of the lot on which the Bell Tower was situated and petitioned to have one hundred dollars appropriated for ground rent since the year 1860. This lot was the small triangular piece bounded by Ramsey, Sherman, and West Seventh Streets. The bell in the tower was rung to mark the working hours and was used also as a fire alarm. Many persons now remember the tower; the bell was removed to the old market house on Seventh and Wabasha Streets.

The Saint Paul Fire and Marine Insurance Company was organized this year with Dr. David Day as president. The reported discovery of gold along the northern boundary of our state caused considerable excitement at this time, and several gold mining companies were organized. The first of these was the Vermillion Falls Gold Mining Company, of which C. Draper Williams was president. Apparently C. D. Williams was a good enough name for a physician, but C. Draper Williams was more impressive on a certificate of gold mining stock.

The salary of the city physician was cut to $150 per annum; inasmuch as gold was quoted at 135 at this time, economy seemed necessary, and as usual the physician suffered. The county commissioners purchased for $1,000 the S. W. ¼ of the S. E. ¼, Sec. 21, Town 29, Range 23, for a poor farm. The only other references of importance enough to note concerning physicians are that on October 3 the funeral of Dr. Ebenezer Miller took place and on the next day the furniture of Dr. Dorphey was sold at auction at his rooms in the Rogers Block. This is the only reference that has been found concerning the latter. It is also stated that on October 8, Borup and Chaplin shipped out six tons of ginseng worth 75 cents a pound.

In November, the board of health was reorganized with Dr. Brisbine as president. He appointed as ward deputies Drs. Steele, Wharton, Willey, Stewart, and Potts. In December Dr. Morton returned from his army service and resumed practice.

It was during this year that Hatch's Battalion captured the two Indians, Shakopee and Medicine Bottle, near Pembina. The captives were brought to Fort Snelling for trial, were convicted and hanged. The story of their fate afterward is best told by quoting from the *Pioneer* for November 16, of the following year.

> About a year ago Shakopee and Medicine Bottle were hanged at Fort Snelling. That night about the bewitching hour of 11 P. M. a light might have been seen through the window of a drug store not many miles from the corner of 7th and Jackson Sts., and the rotund form of Dick C—— (we omit names) busily engaged in packing Mr. Shakopee in a cask of spirits. The next chapter in the romance was an item in a Philadelphia paper stating that Shakopee's body had been received and duly dissected at a medical college in that city. But what of Mr. Bottle? We suspect the Ramsey County Medical Society can tell what became of his flesh. As for his skeleton, we saw it in the office of a surgeon down street the other day, and a fine framework of bones Mr. Bottle had, too.

The editor anticipated the founding of the Ramsey County Medical Society by three years. He probably referred to the Saint Paul Academy of Medicine and Surgery. That society suspended sometime in 1866. At any rate, one must give the editor of the *Pioneer* the credit of naming the Ramsey County society even before its conception.

1866

The outstanding event of 1866 was the reappearance of Asiatic cholera in Saint Paul. The ravages of the disease and the efforts made by the board of health to cope with it are considered in a separate chapter, and will not therefore be described here.

Dr. Morton, who had returned from army service late in 1865, died in Saint Paul on March 22, and the papers gave a long account of his army services and his career. He was the first of the group of medical men who came to Saint Paul in the previous decade to pass away. The papers also recorded, on January 27, the death of Dr. Hiram Murdock, at the residence of Dr. Henry Murdock in Taylor's Falls. He was born in New York in 1797. He was the father of Judge H. L. Murdock, of Saint Paul. The papers stated that he was formerly a resident of the city, although there is no record that he ever practiced his profession there.

Early in the year the Cosmopolitan Hotel at Third and Franklin Streets burned, but the stone walls remained standing until the night of June 25, when a violent wind storm blew them down, demolishing the house next door, which was occupied by Dr. Schell. It was feared that the doctor was killed, but those who started to clear away the ruins were encouraged by a flood of expletives in his well known voice. When he was extricated, it was found that his left leg had sustained a compound fracture which confined him to bed for some months.

In February Dr. Tavenier, who had been away for some years, returned to Saint Paul. Dr. D. W. Hand returned from army service in June and resumed his practice with Dr. Willey, and Dr. Thomas Foster also returned. Dr. Vaiden, who had been in Saint Paul since 1854, moved to Prescott, Wisconsin, where he purchased a large tract of land. Dr. Peter Gabrielsen, who had received his discharge from the army, evidently could not give up the fighting habit, and was twice arrested for assault and fined in the police court. For further particulars regarding him see the biographical section.

Among the new physicians who came to Saint Paul were Dr. Charles E. Smith, who had just finished a year of interneship at the Pennsylvania Hospital, after graduating from the University of Pennsylvania. He began practice with his father, Dr. Franklin R. Smith. Dr. James T. Alley, a homeopathic physician, came from New York. He obtained considerable practice and died in Saint

Paul September 17, 1878. A Dr. Edward Wietfeldt also arrived during the year but remained only a short time. Dr. Cyrus Brooks left the army and became a sanitary inspector for the second ward. Dr. Samuel D. Flagg became a permanent resident, probably shortly after the beginning of the year. In March he was appointed by the governor to the board of managers of the state lunatic asylum, a newly created board. Dr. J. V. Daniels, of Saint Peter, was president, and Dr. Flagg, secretary. Several itinerant medical practitioners spent a short time in Saint Paul as in previous years, but their names are not important enough to record.

An income tax was passed by Congress at this time and it may be of interest to record the incomes of some of our medical men. Incomes over $600 and under $5,000 were taxed 5 per cent, and over $5,000, 10 per cent. The amounts given include the $600 exempt.

A. G. Brisbine	$1,208.00
Wm. Caine	900.00
David Day	1,462.00
Samuel D. Flagg	855.00
J. H. Murphy	1,000.00
J. H. Stewart	1,114.00
F. R. Smith	1,100.00
John Steele	1,174.00
T. C. Schell	959.00
Godfried Stein	674.00
C. D. Williams	1,535.00
H. Wedelstaedt	725.00
Alfred Wharton	1,028.00
Samuel Willey	1,098.00

These amounts probably represent the total income. The returns show that there were only 475 persons in Ramsey County with incomes over $600 and only 206 in Hennepin County. Day was in the drug business at that time and Stein was also a druggist. The last named lived in Saint Paul many years and finally returned to Germany. Dr. George Stein, a son, is now practicing medicine in Munich.

The ginseng business in 1866 was slightly in excess of that of the previous year, as 89,523 pounds were shipped out of Saint Paul. It was ginseng that stimulated the trade with China and which resuscitated the country after the Revolutionary War, and it seems fair to believe that this trade helped the residents of Minnesota after the Civil War.

The Saint Paul Academy of Medicine and Surgery, which was organized in 1860, passed out of existence this year. There seem to have been several causes for its demise. Morton was dead and Rieger had moved away. The Academy lost the position of city and county physician and health officer which had been a principal source of income, though the emoluments of the position were greatly reduced. Most of the members had been away in the army during the previous years. Stewart and Wharton were at outs. Stewart and Murphy could not agree, as Stewart's ambitions were political and he was afraid of Murphy, who had much prestige among the ex-soldiers. It was necessary also for the physicians to build up their finances and the Academy was expensive. In addition the organization was rather a closed corporation and new men who had arrived in Saint Paul thought they ought to be taken in, but their professional status had as yet not been determined. Finally a meeting was held, the library was distributed by returning the books to their donors, the laboratory apparatus was sold, the balance of the funds was expended for an elaborate banquet, and the Academy was thus "liquidated and dissolved."

1867

In a summary of the previous year's health, the papers stated that 1866 had been the healthiest in the history of the city and suggested that the cleaning up of the city again be undertaken. In April, Brewer Mattocks was elected city physician and a general cleaning up of the city was begun. The quarantine station at Pig's Eye was equipped for use, should an emergency arise, and the smallpox hospital was moved to that locality. The mortality statistics showed that 272 deaths had occurred in Saint Paul the previous year. The population was between fourteen and fifteen thousand. This year the legislature passed general regulations for the reporting of births, deaths, and contagious diseases, which were almost similar to those put in force in Saint Paul the previous year.

One of the most interesting events in Saint Paul history, and of international aspect, occurred this year. The trial of one "Dr. George L. Van Solen, M.D." for the murder of a Dr. Harcourt. Harcourt was an Englishman and resided in Saint Louis. In 1865 he came to Saint Paul and went on a hunting expedition with Van Solen. Van Solen returned alone saying that Harcourt had deserted him. Nothing was thought about this event till 1867, when Harcourt's relatives in England, not having heard from him, asked the State Department to investigate his disappearance. It was then remembered that in 1865 a body had been found in the river at Pig's Eye with a stone tied to the neck, evidently a murder. Van Solen was found in Chicago, arrested for the murder of Harcourt and tried in Saint Paul. This was the longest and most expensive trial held in Saint Paul up to that time. The first trial ended in a disagreement; after a second trial, in 1868, Van Solen was acquitted. The prosecution was unable to prove that the exhumed body was that of Harcourt. Every physician in Saint Paul testified in the trial, but as the exhumed body was badly decomposed, their testimony was somewhat at variance. It was brought out at the trial, however, that Van Solen was a self-styled physician, a mechanic by trade, but that he had been a hospital steward in the army under Dr. Wharton.

In May, Dr. Brisbine was elected county physician, but in June the county commissioners again declared the office vacant and elected Drs. Murphy and Wharton to fill the position. The first reported malpractice suit against a physician occurred this year, Dr. Stewart being the victim; the jury found for the defendant.

A large number of physicians and so-called physicians came to Saint Paul in 1867. The majority remained but a short time, and were cancer specialists, magnetic healers, venders of spectacles, corn doctors, and the like. A Dr. H. Willson who had been surgeon to the Sixth Regiment essayed the practice of medicine in Saint Paul after practicing at Chatfield for a short time before the war. A Dr. N. Stanton, also, who stated he had had an extensive experience with cholera in 1851, and who gave Drs. Hill and Lindley of Minneapolis and Drs. Stoneman, Talvert and White of Saint Anthony as references, remained a short time. A Dr. Clark of Troy, New York, a homeopath, attended to Dr. C. D. Williams' practice during the latter's absence from the city. Dr. E. Herman Smith, a young man of great promise, who had just served an internship at Bellevue Hospital, New York, came to Saint Paul at this time largely because of his health. He became very popular and was one of the founders of the Ramsey County Medical Society in 1870. He returned to his home in Massachusetts early in the next decade and died there of tuberculosis. Dr. William Ray came to Saint Paul this year. He also was one of the founders of the society. Dr. Thaddeus Williams, of the Galenic Institute, moved temporarily to Janesville, Wisconsin, to open a drug store. The papers stated that he wrote literary articles under the name of Gordon Revere, and was the author of the article on the climate of Minnesota in Colonel Hewitt's immigration pamphlet. He left his younger brother, Dr. Cornelius Williams, in charge of the Galenic Institute for two years.

On February 14, 1867, the Minnesota Homeopathic Institute was incorporated in Saint Paul, with Dr. H. Wedelstaedt as incorporator and secretary. The officers were: C. D. Williams, president, St. Paul; W. H. Leonard, first vice president, Minneapolis; Z. B. Nichols, second vice president, Faribault; H. Wedelstaedt, recording secretary, St. Paul; T. R. Huntington, corresponding secretary, Minneapolis. The Board of Censors was composed of: J. N. Wheat, T. R. Huntington, and J. T. Alley.

The manuscript minutes of this society for the years 1867 to 1884 and from 1906 to 1912, when it dissolved, may be found in the Library of the Minnesota Historical Society.

It may be of interest to give here the incomes of some of the Saint Paul physicians as filed for the year ending May 1, 1867. The amounts include the one thousand dollars exempt.

David Day	$1,223.00	F. R. Smith	$1,955.00
S. D. Flagg	1,497.00	J. Steele	1,157.00
D. W. Hand	1,509.00	A. Wharton	1,600.00
J. H. Murphy	1,500.00	Samuel Willey	1,354.00
Russel Post	3,794.00	C. D. Williams	1,479.00
J. H. Stewart	5,250.00		

1868

Other than the Van Solen murder trial already mentioned there seems to have been little of medical interest going on in Saint Paul this year. The usual number of advertising doctors were in evidence, who after blatantly advertising their phenomenal skill, remained for a short time and then passed on to other fields. Among the physicians who settled in Saint Paul more or less permanently were Martin Hagan, who may have come late in the previous year, and Adelard Guernon, a French Canadian, who succeeded to Dr. Vervais' practice, Vervais having died from an overdose of morphine on October 10. Hagan did well and remained a number of years. Both he and Guernon were admitted as charter members of the Ramsey County Medical Society.

Two homeopathic physicians, Dr. J. B. Hall, of Cleveland, Ohio, and Dr. B. J. Adams, chose Saint Paul for their field of endeavor. Also recorded as residents of Saint Paul are Dr. C. A. Glidden and Dr. Henry H. Eames. The former, a homeopath, remained about twenty years; nothing is known of the latter. Another man whose history is unknown is of more than passing interest. On October 23 the *Pioneer* published the card of Dr. P. Ronning, Norwegian physician, Office 130 Third Street. The name in another place is spelled Roëning. As he was the first of his nationality to practice medicine in Saint Paul, it would be desirable to learn more about him. Apparently he remained but a short time. The papers also recorded the death from apoplexy of Dr. Wm. P. Lambert, U. S. A., on April 28, at the home of his brother, Judge Lambert. Two Drs. Lambert have previously been recorded as practicing in Saint Paul and apparently they were all related. This Dr. Lambert was stated to have been born in Huntington County, Pennsylvania. He was fifty-three years of age at the time of his death, and had been a surgeon in the army and navy since the age of twenty. He probably was not a resident of Saint Paul. Drs. Stewart and Mattocks dissolved partnership at the beginning of the year, and Dr. C. E. Smith was elected county physician in June. M. G. T. Daly, son of Thomas Daly of Saint Paul, graduated in medicine at McGill University in May.

The incomes of some of the Saint Paul physicians for the year ending May 1 is given as follows:

A. G. Brisbine	$1,100.00	John Steele	$1,856.00
David Day	1,230.00	J. H. Stewart	5,530.00
D. W. Hand	1,356.00	F. R. Smith	1,636.00
Brewer Mattocks	1,339.00	A. Wharton	1,700.00
J. H. Murphy	1,500.00		

It is interesting to compare these figures with those of previous years. Apparently the practice of medicine was not very lucrative but of course the overhead costs were low in comparison with those of today. Stewart always managed to hold some lucrative office which added to his income from medical practice. C. P. and D. R. Noyes came to Saint Paul this year and took over the wholesale drug business formerly owned by Vawter, Pett, and Moulton.

1869

The year 1869 was an important period in Minnesota medical history. The earliest event of the year was the organization or reorganization of the Minnesota Medical Society under the name Minnesota State Medical Society. The call for the meeting was published in the Saint Paul papers on January 20 and 21, as follows:

> Minnesota Medical Society
>
> A meeting of the Society will be held on Tuesday, February 2nd, 1869, at the International Hotel in St. Paul at 11 A. M. County and City Medical Societies throughout the state are requested to send delegates.
>
> Business of importance will be presented.
>
> Thos. R. Potts, M.D.
> F. R. Smith, M.D.
> J. H. Stewart, M.D.
> A. E. Ames, M.D.
> J. H. Murphy, M.D.
>
> Minnesota papers please copy.

The meeting was held as announced on February second and third. Two paragraphs from the *Pioneer* of the third regarding this meeting may be quoted.

> About two years before Minnesota became a State, that is in December, 1855, a State Medical Society was organized in Saint Paul, by adopting a constitution and by-laws and the election of the following officers:
>
> President—Dr. T. R. Potts
> Vice President—Dr. J. H. Murphy
> Recording Secretary—Dr. J. V. Wren
> Corresponding Secretary—Dr. J. D. Goodrich
> Treasurer—Dr. David Day
> Censors—Drs. W. H. Morton, F. R. Smith, J. H. Stewart, A. E. Johnson, and A. E. Ames.
>
> Two subsequent meetings were held, the last being at St. Anthony in 1857. After that period the Society was allowed to languish.

In the account of the old Society to be found in this sketch for the year 1853, it is shown that whoever gave this information to the paper had a bad memory, as the Society was organized in 1853, reorganized in January, 1856, and that the names of the officers here given are those of 1857.

The history of our Minnesota State Medical Association, as it is now called, is not within the province of this paper, but it might be pertinent to attempt to surmise what the "business of importance" was which caused the call for the meeting. It is evident that the time was thought auspicious for securing the passage of a medical practice act by the legislature. This movement was successful, for on March 4 the legislature passed a law of six sections regulating the practice of medicine. We give here in abbreviated form Section I (see Samuel Willey in Medical Record, Vol. IV, p. 86, Apr. 15, 1869):

> "That it shall be unlawful for any person, within the limits of said State, who has not attended at least two full courses of instruction and graduated at some school of medicine within the United States, or of some foreign country, or who cannot produce a certificate of qualification from some state, district or county Medical Society . . . to practice medicine in any of its departments . . . within the said State of Minnesota."

It was hoped that this law would bar advertising quacks and irregular practitioners from the state. The promulgators of the law were disappointed. In the first place there was no adequate means of determining whether a diploma presented was forged or stolen, and furthermore, the country was overrun with obscure and inadequate medical schools and diploma mills. Lastly, and still more aggravating, was the fact, discovered after the law was passed, that the articles of incorporation of the Minnesota State Homeopathic Institute formed in 1867 gave that society the same right as a medical school of conferring the degree of Doctor of Medicine. While the gentlemen of this latter society were to be commended for their acuteness in securing this power, they were not acute enough to restrict the issuing of their diplomas to their own kind. Every quack who signified his belief or preference for homeopathic practice was welcomed with open arms, and they felt that their school of medicine was making great progress. The result was that the same men who worked to influence the legislature to pass this act worked just as hard to have it repealed at the next legislative session. This was done and Minnesota had to wait till 1883 before another Medical Practice Act was put on the statute books.

The meeting of the State Medical Society was held as stated at the International Hotel, which was on the corner of Seventh and Jackson Streets. The members retired on the third (no doubt well satisfied and tired out), but not to rest, for at five o'clock on the morning of the fourth the hotel burned. Drs. Hagan and Flagg, who were residents of the hotel, managed to save some of their belongings, and a dozen or more of the out-of-town physicians escaped with small or no losses and uninjured.

The state Medical Society was not the only medical society to organize this year, for the press published on May 20, "A call for a mass convention of Eclectic Physicians in Minnesota," as follows:

> "We, the undersigned, deeming it important to Eclectic Physicians of Minnesota and for the better procution (sic) of our principles, and the advancement of Medical Science, would request all physicians who hold to the Eclectic Practice of Medicine to meet with us at the City of Owatonna, Wednesday, the 26th of May, for the purpose of organizing a State Eclectic Medical Society.
>
> E. M. Morehouse — E. P. Kermott
> N. S. Culver — Thos. More
> L. F. Case — F. Lee."

(To be continued in May issue)

President's Letter

OUR Public Relations constitute a problem of great difficulty at the present time. The medical profession is more or less on the "spot"; the same thing happens at different epochs to any professional, business or labor group. At such times, propaganda comes into play.

Propaganda is justifiable, of course. As doctors, as citizens, it is not only our right but our duty to present our beliefs and we cannot deny to those who do not agree with us the same rights and privileges. The difficulty is that the medical profession has had no training in propaganda. Essentially we are practicing physicians, teachers, research workers or administrators, and propaganda is a separate specialty just as surely as any other activity in life.

Because of our inexperience and lack of training, we may at times show at a disadvantage in any conflict of opinion that comes to the attention of the public, whether over the radio, in the newspaper, in public meetings, and even in individual conversations with lay people. Still our viewpoints must be presented.

As stated before, propaganda in the right sense is an honorable and just procedure. Our best propaganda keeps continually before the public the fact that our primary interest is in the public health, that our primary work is the practice of medicine, and that our welfare is identical with the welfare of the people.

The County Officers' meeting recently held in Saint Paul was of unusual interest and merit in this connection. Representatives from the press, the radio, the Department of Public Speaking at the University were there, also representatives of other interests with whom we are constantly in contact. They gave their lay viewpoints; viewpoints which we must understand if we are going to make progress in presenting our own views. At times we do not agree with what such persons tell us, but we should get their viewpoints and it might be of great value to any county society to arrange programs of this kind.

The State Office is pleased over the commendatory remarks we are receiving on the program of the month. Doctors who have never before written to the State Office have requested material.

Our State Medical Association meeting will be held May 31, June 1 and 2. The first two days will be strictly scientific. We believe that the exhibits and demonstrations will be unusually good, as well as the program for these two days.

A Public Health Exposition will be held in conjunction with the meeting. Our associates in health, including the dentists, the pharmacists, hospitals, hospital administrators, nurses, the Minnesota Public Health Association, The Women's Field Army against Cancer, the State Board of Health, the State Board of Control and others will be represented. This Exposition is undoubtedly in line with our best type of public contact.

The program for the third day will deal still further with our public contacts. It will take the form of a conference on medical problems in which well-known lay and medical authorities from the United States and Canada will participate.

George Earl, M.D., *President*
Minnesota State Medical Association

SULFAPYRIDINE

MOST clinical investigators are of the opinion that sulfanilamide alone is of doubtful value in the treatment of patients with pneumococcus pneumonia. Therefore, much interest accompanied the announcement of Whitby in 1938 that a chemical compound closely related to sulfanilamide had proved effective against various strains of pneumococci. This new compound differed from sulfanilamide in that one hydrogen atom of the SO_2NH_2 radical was replaced by a basic pyridine group. Known in England as M & B 693, this product has been recently placed on the market in this country as sulfapyridine.

The new Federal Food and Drug Law prohibits the sale of any new drug until it has been adequately investigated clinically and experimentally. In this manner, sulfapyridine has been used at the University of Minnesota Hospital during the past six months. The drug was supplied by Merck and Company in the form of uncoated 0.5 gram tablets. Patients treated with sulfapyridine at the University Hospital included the following general groups: those with pneumococcus pneumonia, staphylococcus sepsis, and subacute bacterial endocarditis. Nearly fifty patients have been given the drug. For the purpose of the present discussion, the following observations have been made: the effect of sulfapyridine on the clinical course of pneumococcus pneumonia; in a few instances, its effect when combined with type specific antipneumococcus serum; the rate and degree of absorption of the drug from the gastro-intestinal tract; the determination of blood levels, including both the free and conjugated forms, and the relationship of these levels to the dose; and the toxic manifestations.

It should be emphasized that, at the present writing, type specific antipneumococcus horse and rabbit serums are the treatment of choice for pneumococcus pneumonia. This is particularly true for those cases with a lobar distribution, and those with a bacteremia. Serum is most effective when given in adequate doses and early in the course of the disease. There is some question as to whether sulfapyridine should be combined with serum therapy. In a small number of cases, specific rabbit serum and sulfapyridine have been administered to adults with a Type III pneumococcus pneumonia, and a bacteremia. The results have been disappointing, due, in part, to the advanced ages of the patients. On the other hand, Finland working at the Boston City Hospital has recently stated, "The action of sulfapyridine and its effect on the course of Type III pneumococcus pneumonia is being assessed. While it is yet too soon to draw final conclusions, the findings suggest that the combination of specific antipneumococcus rabbit serum and sulfapyridine exerts an optimum effect, both *in vitro* and in the patient."

It would appear from the observations at the University Hospital and elsewhere, that sulfapyridine is definitely useful in certain groups of patients with pneumococcus pneumonia. The first group includes young adults with minimal lung involvement caused by one of the higher pneumococcus types, and with negative blood cultures. They appear to do well following sulfapyridine therapy.

Likewise, there is evidence that the drug is of value in children over the age of two. The mortality rate of pneumococcus pneumonia in children of this age group is generally considered to be low, and there are indications that sulfapyridine therapy will be adequate for those cases without a bacteremia, and a limited involvement of one lobe. The drug has been administered to post-partum and post-operative patients who have had an atelectasis limited to a small area of one lobe and who have also had the signs and symptoms of a beginning pneumonia with small numbers of pneumococci of one of the higher types in the sputum. The blood cultures have been sterile. Under these circumstances, sulfapyridine has been given, and coincident with its administration the patients have improved. Occasionally, a patient is encountered having the classical signs and symptoms of lobar pneumonia, but the biological agent causing the disease cannot be isolated. Sometimes in these cases, sputum adequate for typing purposes cannot be obtained. Under these and similar conditions, one may be justified in administering sulfapyridine. It should be stated that in several instances when the drug was given to patients ill with pneumonia, it had to be discontinued because of toxic manifestations as described below. One of the outstanding features of serum treated patients is that when the temperature approaches normal they feel considerably improved. This is not so obvious in the sulfapyridine treated patient. The temperature may be normal, but the patient does not appear or feel well.

During the present winter, many cases of atypical pneumonia have been encountered, and, largely because bacteriological studies have not yielded a causative organism, the disease has been assumed to be due to a filtrable virus. Sulfapyridine has been given to these patients with no apparent benefit. Other cases with a consolidation of the lung due to a hemolytic streptococcus have responded well to sulfanilamide.

There is no definite rule concerning the dosage. It should be remembered that sulfapyridine is highly insoluble, and for that reason no preparation is available for parenteral injection. Whitby has recommended doses in adults of 5 grams within 12 hours, in lots of 2 grams, 2 grams, and 1 gram four-hourly, and then 1 gram every 4 hours, night and day. With this dose, a blood level of 8 to 10 mgs. of the free form may be maintained in most patients. Ten grains of sodium bicarbonate are given with each dose, and whether this is necessary, only further observations will tell. Approximately one-half the adult dose is prescribed for children between the ages of 2 and 12 years, and about one-third the adult dose for infants. Like sulfanilamide, children tolerate sulfapyridine better than adults. The foregoing doses may be continued for several days while the patient is febrile, and then after the temperature is normal the drug may be continued for two or three more days. If the patient is unable to swallow voluntarily, the drug may be administered through a stomach tube by grinding up the tablets and suspending them in water.

It has been found that sulfapyridine is absorbed more irregularly than sulfanilamide, so that it is difficult to maintain constant elevated levels in the blood. Furthermore, in the average patient approximately fifty per cent of the drug present in the blood stream is in the conjugated form. Because of the irregularity in absorption and the large amount that is conjugated (sometimes up to eighty per cent), it is necessary to carry out frequent determinations of the blood level for the free form. This is done by the same method as for sulfanilamide, except that sulfapyridine standards are used. The levels of the drug in pleural exudates and spinal fluids is approximately one-half to two-thirds of that found in the blood. The drug is eliminated from the body within 24 to 48 hours.

The toxic manifestations of sulfapyridine have not been as thoroughly studied as those of sulfanilamide. The outstanding toxic symptoms are nausea and vomiting, and such symptoms occur much more frequently than during sulfanilamide therapy. This vomiting may be a serious complication in a patient quite ill with pneumonia. In some individuals, the vomiting may follow the initial doses, but the patient may tolerate subsequent doses. Other frequent symptoms due to the drug are headache, anorexia, weakness, and a depressed feeling. Mental confusion has been observed. Although cyanosis, as a result of sulfapyridine therapy, had been reported by some investigators, the writer has not observed this phenomenon in any patient treated with the drug. Acute hemolytic anemia, leukopenia, and agranulocytosis have been reported as complications. Drug fever and dermatitis may occur. It is of interest that Whitby has stated sulfapyridine is less toxic for mice than sulfanilamide, whereas Marshall and his associates at Johns Hopkins University have found sulfapyridine more toxic for mice.

It would appear, for the present time at least, that it is more difficult to administer sulfapyridine to a patient than sulfanilamide because of the troublesome vomiting and its irregularity of absorption, and because its insolubility precludes its use parenterally. Although sulfapyridine is effective against the gonococcus, meningococcus, and hemolytic streptococcus, sulfanilamide is equally as effective, and may be administered with less difficulty. For the time being, sulfapyridine should be used only in those diseases where it has been found to be more effective than sulfanilamide. This includes pneumococcus infections and possibly staphylococcal sepsis.

PROGRESS IN THE CONTROL OF CANCER

The unknown horizons of cancer are being pushed back farther and farther through the three closely related activities of clinical diagnosis and treatment, research, and education. Each of these is making significant contributions to a wider understanding of the problems of malignancy. One of the most interesting aspects of the entire cancer problem is that practically every bit of additional information about the disease adds to the hopefulness of its eventual control as a major cause of death.

Realization by the medical profession that the diagnosis and treatment of cancer is no longer a one man problem is offering much additional hope to the cancer patient. The value of organized tumor clinics in general hospitals, nearly three hundred of which are now functioning, is bringing a better appreciation of the complexities of this problem in modern medical practice. These clinics offer help to the family physician who is often denied access to necessary diagnostic and therapeutic facilities; while to the cancer patient it gives the benefits of group consultations with those having the widest experience with malignant disease.

An additional advantage of the tumor clinic is its usefulness as a center for graduate study for all physicians within its sphere of influence. This is possible largely because of the increased number of cancer patients seen in comparison with the relatively small number of such patients seen in the average general hospital. The value of comparative methods of treatment can be established much sooner where large numbers of patients are seen. All in all, the tumor clinic offers the maximum of good service to the cancer patient and excellent opportunities for education of the physician.

In the field of research, some of the most significant contributions to our knowledge about cancer are being made in the sciences of biology, chemistry, physics, and genetics. The rôle of certain chemicals—now numbering approximately fifty with more being added at frequent intervals—in the etiology of cancer is now fully appreciated. The knowledge that cancer is primarily a biological problem concerned with the vital function of cell growth is stimulating research workers to focus attention on the cell to identify those forces responsible for malignant changes in the cell.

Cancer research today is concerned more and more with the chemical nature of cell activity and inquiry is being actively pushed in the field of biochemical investigations. Wide researches are under way to find those chemicals with the most potent influence on normal and abnormal cell activity.

The physicist is extending knowledge of irradiation therapy, with the result that increasing use is being made of this therapeutic agent in the treatment of malignancy both for curative and palliative purposes.

Studies in genetics have been confined largely to work with laboratory animals. The further this work progresses the more evident it becomes that vastly improved records of human cancer are essential if we are to know more accurately the influence of heredity on cancer development in the human race. Because the great majority of marriages bring about a dilution of the probability of transmitting cancer to offspring through susceptible parents, most geneticists are unwilling to go beyond recognition of the possible transmission of susceptibility to cancer in succeeding generations. Even though cancer may be proved to be conditioned by heredity, the rapidly expanding appreciation of the value of early diagnosis and prompt treatment will continue to offer much hope to the cancer patient and will more than offset such handicaps as heredity may impose.

The greatest advance in cancer education of the public has been the organization of the Women's Field Army of the American Society for the Control of Cancer. This organization now extends to forty-six states, of which our own was among the first to be included. Its objectives are to bring to the general public the known and accepted facts about cancer and methods for its control. The presentation of these facts by the medical profession to hundreds of audiences has caused thousands of persons for the first time to seek examinations to determine their freedom from this disease. It has caused thousands of others to replace their unreasoning fear of the disease with an intelligent caution toward this question.

The value of this educational program cannot be fully measured, but the medical profession is in a position to know better than any one else the results of this program as their patients come in increasing numbers with questions about this disease. Success of this educational work rests in large measure on full coöperation by the medical profession. As the objectives of periodic examination and recognition of the early signs of cancer become better understood, a fuller coöperation on the part of the physician will be expected.

The outlook for controlling the increased number of deaths from cancer in this state is becoming brighter. That fortunate time will be hastened in proportion to the coöperation that is developed between the patient and his physician. Education will reduce the waiting period by the patient in seeking professional advice and service. The physician will make his contribution by not delaying in diagnosis and treatment once the condition is brought to his attention.

Frank Rector, M.D.

Field Representative of the American Society for the Control of Cancer.

TUBERCULOSIS CAMPAIGN

EACH year an intensive nationwide campaign for the early recognition of tuberculosis is carried on, not only among the laity but with the medical profession. In spite of the marked reduction in mortality from tuberculosis in recent years, the fact that about two hundred deaths from the disease occur daily indicates the need for continued endeavor on the part of the public and physicians to detect the infection in its early and curable stage.

Early symptoms of fatigue, loss of weight, slight elevation of temperature, and cough, demand the tuberculin test and use of the x-ray if early infection is to be diagnosed. Cough in a young girl may easily be attributed to cigarette smoking and in individuals over sixty to chronic bronchitis or emphysema. These elderly individuals with active tuberculosis are a real source of danger to their young grandchildren. It is also well to remember that the mortality and presence of infection in the colored race is three times that in white people.

In Minnesota, the tuberculosis campaign is directed by the Minnesota Public Health Association and free literature is available to all physicians on request.

THE WAGNER BILL

THE Wagner bill, embodying the proposals of the Interdepartmental Committee appointed by the President of the United States, was submitted to Congress, February 28, 1939. If passed, it will involve the expenditure of millions of the taxpayers' money beginning with eighty million the first year and in ten years' time amounting to 850 millions a year, half of this to be in the nature of a federal subsidy to be matched by the states. This expenditure is proposed according to the provisions of the bill for expanding state programs for (1) child and maternal care; (2) general public health services and investigations; (3) construction of needed hospitals and health centers; (4) general programs of medical care; (5) *insurance against loss of wages during periods of temporary disability.*

It is generally agreed that government activity in health matters is necessary in the prevention of epidemics and in matters affecting the health of its citizens in the general sphere of prevention. It is also generally agreed that there is need for financial assistance from the states in the care of the tuberculous and insane and those afflicted with venereal disease where care of the sick is closely bound up with prevention of disease. The governmental units have, generally speaking, not invaded the field of curative medicine, except in the care of the indigent. One outstanding exception has been the opening of Veterans' hospitals to former veterans for the treatment of conditions in no way related to government service which was a gross trespass in the field of private practice.

Now, the federal government proposes in the Wagner bill to expand certain public health activities to which the medical profession, through its national organization, has agreed. But, in addition, the bill proposes the construction of hospitals and medical centers which are not extensions of present government activities, but will constitute competition with present private hospitals, which have in general had great difficulties in recent years to keep going. If the federal government provides funds for the construction and maintenance of hospitals, their placement and management will be subject to political control. We have but to review the history of postoffice construction and management to visualize what can happen in the case of hospitals.

Doubtless, some localities suffer from insufficient medical care. Is this, however, not a local city, county or state problem, rather than a federal one?

Most serious-minded citizens believe that the balancing of federal and state budgets is of present vital importance. If budgets are to be balanced, not only will present federal appropriations have to be scaled down to the tune of some four billions of dollars a year, but the government will have to resist the temptation to launch new and expensive innovations such as those involved in the Wagner bill.

The proposals of the Wagner bill are those made not by Congress, but by the President's Interdepartmental Committee at the so-called conference held last July in Washington. The members of the medical profession had scant recognition; business men who will have to largely foot the bill had no representation. The proposals make some emotional plea to the public. Who can vote against a measure providing for more medical care for mothers and children and face their home constituents?

Perhaps the optimistic can see some hopeful signs of retrenchment on the part of Congress in this vital matter of federal expenditures. The fate of the Wagner bill will afford some indication of the trend. It is not generally appreciated that our representatives in Congress are largely influenced by their constituents at home. Each voter has a duty and privilege which he should exercise now by writing his senators and representatives in Washington, and by inducing his friends to do the same, expressing his opinion that the Wagner bill should be carefully considered and greatly pruned before it is allowed to pass. Do it now!

"Lord Nuffield, manufacturer of Morris cars, and far-seeing student of the relation of theory to practical purpose, recently offered Oxford a million-and-a-quarter pounds for medical research. When the vice-chancellor formally accepted the gift, Nuffield ventured to increase it without warning to two million pounds. In donating this enormous sum, he emphasized the importance of providing permanently for scientific advance and direct application of these advances to medical practice.

"I have the story from a friend of Nuffield's that one of the things that led him to want to contribute to the work of the medical profession was an early meeting with that great Canadian, Sir William Osler, who was then Regius Professor of Medicine at Oxford. Sir William had brought his automobile into the Morris garage for repairs of an urgent nature. He hardly guessed that in the person of the alert young owner of the garage he was talking with the man who would do more than anyone else to further the ambitions which he had for medicine at Oxford. No doubt it was the cordial personal interest and humour for which the older man was famous that led the then Mr. Morris to see to it that the car was ready the following morning after a night of labour, and to remember a friendship thus begun.

"It is doubly curious that this great English benefactor should recall this small Oslerian incident in connection with his benefaction, for it has been recorded that the late John D. Rockefeller, Senior, who gave so generously to medicine throughout the world, conceived the idea of organized endowment of medical research after Osler's textbook of medicine had been called to his attention, with its searching tabulation of what was known and what was unknown in the treatment of disease.

"Hard on the heels of his own gift to medicine Nuffield set aside another million pounds to create a new college at Oxford to be devoted to political science."

—Penfield, Wilder: Medicine and other things. *The McGill News,* 20:16, 1939.

MEDICAL ECONOMICS

Edited by the Committee on Medical Economics
of the
Minnesota State Medical Association
W. F. Braasch, M.D., Chairman

MEDICINE IN MINNESOTA

An interesting picture of the status of medicine and the public health in Minnesota was drawn by committee chairmen and representatives of agencies concerned in the delivery of medical services at the breakfast session.

Brief statements are quoted below from the 500-word reports of these officials.

Dr. S. E. Gilkey, medical director, State Relief Administration: Medical care for relief clients in Minnesota is becoming standardized to a degree that is proving beneficial to the client, *without prejudice to the taxpayer or the health professions.*

Clarification Needed

Mr. B. E. Youngdahl, director of the Division of Public Assistance, State Board of Control: Considerable clarification is still necessary in our relief legislation if we are to achieve an orderly procedure in the provision of medical care for the needy. There is confusion due to the categorical system of relief and aid giving, due to the large number of government units involved, due also to two types of relief giving—the township and the county systems—and to the maximums set in the public assistance act.

Whatever proposals may be made to the legislature to clarify this situation, it is my belief that the free-choice-of-physician-principle should be maintained. The patience and coöperation of the medical profession has aided materially in the handling of medical care for the needy.

Compensation Costs Are Low

Mr. G. L. Stolte, deputy administrator of WPA in Minnesota: In the event of an emergency outside of work, WPA workers must depend upon supplemental aid from respective County Welfare Boards. In the event of injury in work status, necessary medical and hospitalization and compensation for extended loss of time from work is provided. Our record in compensation costs in relation to payroll expenditures is very low compared with the expectancy rating which would be set up in private activity. We have been averaging 50 cents for every $100 payroll and regular insurance rates for similar coverage through private channels would vary from $4 to $10, depending on the type of work covered. Medical and hospital expenditures to date have approximated $325,000, and, at our present rate of employment, averages about $9,000 per month. In other words, 60 cents in every compensation dollar goes for medical and hospital care. Care for WPA injuries is distributed as equally as possible among eligible hospitals and doctors.

Services for Crippled Children

Dr. H. E. Hilleboe, Director of Services for Crippled Children, State Board of Control: The program of the Division of Services for Crippled children carried out under medical direction, without political or governmental interference, gives real evidence of what can be accomplished by the medical profession in the field of public health and welfare for the permanent benefit of youthful citizens in need of care. The state register comprising orthopedically crippled children under 21 years of age in Minnesota included 9,094 cases on January 1, 1939. On July 1, 1937, there were only 6,039 cases on the register. A large number of new cases are reported by general practitioners through the field nursing and clinic service.

Fourteen itinerant field clinics are held each year throughout the state. This is one of the most effective means of finding crippled children early, of determining the need for care, following up treated cases locally and of public health education. Twenty-three per cent of the 1,264 examinations made in the clinics were new to the register, and predominantly in the younger age groups. The nursing and field service have been doing invaluable work in finding cases, in education and follow-up, in meeting the nursing and social needs which augment medical care given. When no beds are available in public hospitals, the youngsters have been hospitalized in private hospitals under the care of qualified orthopedic surgeons within the limits of funds available.

Since the start of the program in 1936 there have been 531 hospitalizations of 364 crippled children in private hospitals at the expense of the Division. During the biennium ending June 30, 1938, $31,188.43 was paid to orthopedic surgeons and consultants as fees for care of crippled children. This is over 19 per cent of the total budget of the division for the biennial period. Refresher courses have been held in county medical societies and in coöperation with the State Board of Health, the division has given a continuation study course for all public health nurses through the state involving 32 lectures at six centers.

Problem of Pre-Maturity

Dr. E. C. Hartley, director of the Division of Maternal and Child Hygiene, State Department of Health: It is worthy of note that while the infant mortality rate has shown a steady decline, most of this decline has taken place in the period following the first month of life, that is, from the second to the twelfth month. In the actual newborn period there has been far less change, and for the first day of life there has been no change at all. The medical profession and the State Health Department are concerned about this lack of improvement. Among the chief causes for these early deaths are found to be prematurity, birth injuries and congenital malformation. In other words, a great bulk of them may be effected favorably in two ways: first, by continually raising the standards of maternal care, and, second, by improvements in the care of premature infants.

New Program

Recently the State Department of Health in coöperation with the State Medical Association and with the State Hospital Association have planned a project aimed directly at improvement in the care of premature infants in Minnesota. The money for this purpose is part of the Social Security fund received by the State Board of Health from the Children's Bureau in Washington. The plan involves the training of a special pediatric nurse in the modern methods of premature care. This nurse has been selected and will receive her training under Dr. Julius Hess of Chicago, who has carried on a considerable amount of work among premature infants and has devised a system of nursing care for these infants which has been eminently successful in reducing the premature death rate in the City of Chicago. When this nurse has completed her special training, she will return to Minnesota and embark at once upon an itinerary, planned for her by the coöperating agencies, which will include most of the Hospitals in the State.

Minnesota has always ranked with the leading two or three states in its infant and maternal mortality rates. Since so large a percentage of even the extremely low rate which now exists is due to prematurity, the agencies involved are extremely hopeful that the successful operation of this project will markedly reduce the present infant mortality rate in Minnesota.

Keeping Abreast in Medicine

Dr. W. A. O'Brien, medical director Center for Continuation Study, University of Minnesota: Since January, 1937, the Center for Continuation Study at the University of Minnesota has conducted 23 courses in post-graduate medical education and six courses in post-graduate hospital education. In the medical field, the average enrollment has been 26 for each course and the average faculty appointments have been 24. In the hospital fields, average enrollment has been 66; average faculty appointments 26. To date, there have been more than 1,000 enrollments in the above courses. This is approximately 25 per cent of the total enrollment for all courses offered at the Center. The main fields are medicine and hospitals, education, social welfare, and professionalized community service. There have been courses in practically every field, including welding for engineers, visual education for teachers, pharmacy for pharmacists, and so forth.

Approximately half of the physicians who attend courses at the Center are from Minnesota. The others are from Wisconsin, North Dakota, South Dakota, Montana, Wyoming, Nebraska, Iowa, Manitoba, Saskatchewan, Illinois, Florida, California, and other states. Approximately half of the physicians have graduated from the University of Minnesota. The median age is 42. In the hospital field, more states are represented. In the course for Hospital Administrators, 91 administrators represented 73 institutions in 52 cities, having a total bed capacity of 10,356 and 994 bassinets. The 87 medical record librarians came from 47 cities in 16 states and represented 71 hospitals with 14,250 beds and 1,684 bassinets.

The average medical course is six days in length; hospital courses are either three or six days. All the courses deal with specialized subjects. In medicine, there are 42 possible specialized courses and there are 38 in the hospital field. It is felt that more information can be obtained by developing a fairly narrow field than by trying to cover too much ground. Much more can be accomplished by helping the hospitals as well as the physicians. In this way, new technics can be more quickly put into effect.

Advantage Obvious

The University of Minnesota now has undergraduate, graduate, and post-graduate departments. In the Medical School proper there are 589 students; Nursing Education—390; Post-graduate Nursing Education—26; Medical Technology—240; Public Health—140; Dietetics—12; Medical Social Service—12; and pharmacy students in the hospital — 40. In the Graduate School, main campus and Mayo Foundation, there are 530 registered in Medical Sciences. The advantage of going to the University for short intensive post-graduate courses is obvious. The physician is able to accomplish a great deal in a short time because he is given a special program in a place reserved just for him. When more physicians in Minnesota take advantage of the opportunities which are now provided, there will be less criticism of the profession for failing to keep abreast of the new advances in medicine.

Industrial Hygiene

Dr. R. N. Barr, State Department of Health: A bill for an act to "provide for the investigation and control of poisoning and disease contracted as a result of the nature of employment and for reporting of such cases of poisoning and disease" has been introduced into the legislature under sponsorship of the State Department of Health and referred to the Public Health and Hospital Committee. It should be noted that the bill not only provides for the reporting of occupational diseases but also provides that the department shall make investigations and recommendations for the elimination and prevention of occupational diseases. Most important of all, it provides that information secured through investigations made in accordance with the provisions of this bill shall not be admissible as evidence in any action of law to recover damages for injury or in actions under the Workmen's Compensation Act. This would mean, simply, that the work of the Department would not be involved in civil suits. It would not in any way limit the authority of the Industrial Commission or any other state agency in enforcing rules and regulations necessary to protect the health of employees. If the bill is passed, it will become possible for the State Board of Health to give organizations and industries a technical service which they are unable to secure at the present time, because they have neither trained personnel nor laboratory equipment with which to carry out such work.

Anticipating the possibilities of this work, the State Board of Health has included in its budget request for the biennium 1939-41 an appropriation of $12,000 per annum to provide for personnel and laboratory expense.

Monthly Program

Dr. J. B. Carey, Minneapolis, chairman of the Committee on Hospitals and Medical Education: The Coördinated Medical and Public Health Program of 1939 of the Minnesota State Medical Association introduces no new activities into our state medical association program. It provides, merely, that all of our public health education work be so organized that all of us are thinking and talking about the same things at the same time. A subject of timely interest has been selected for each month and, during that month, our newspaper, radio, and speakers' bureau service is all directed toward education on various phases of that subject. In addition, a packet of new material designed to aid the doctor in talking privately or publicly on the subject is sent by the State Office on request to any member of the association.

Packet Popular

The program seems to be popular with our members as well as with the public. More than 723 requests have been received at the State Office for the packet. A large number of talks have been booked and many other agencies such as the Federation of Women's Clubs, the Congress of Parents and Teachers and others, have welcomed it and incorporated it into their own health programs. Our thanks are due to the State Department of Health for the splendid co-operation of every division in supplying material and advice for monthly packets.

THE DOCTOR TAKES THE AIR

County officers listened with great interest to the symposium on forming public opinion which was one of the highlights of the 1939 County Officers' Conference at the St. Paul Hotel, Saturday, February 25.

New radio stations are opening up all over the state and most of them are willing and anxious to arrange for medical broadcasts. Requests for public talks on health and on medical problems are also frequent and insistent in many parts of the state. Every physician knows he will be called upon, sooner or later, to make a speech and he is wise to prepare himself.

For Platform Talks

The following hints for the platform speaker were given in an excellent talk by Dr. Howard Gilkinson, University of Minnesota Speech Department.

1. Plan for clearness. Talk about one thing at a time and make clear transitions from one topic to another.

2. If possible, use visual aids. Visual aids and oral discussion are more effective together than either one alone. The order should be, first, introductory remarks; second, picture or slide; third, discussion.

Vary Your Voice

3. Never be a vocal dead pan. Vary your pitch and the quality and intensity of your voice.

4. For emphasis, pause before and after an important statement. If necessary, repeat it once or twice. Four or five repetitions, however, are outlawed. Remember that statements made at the beginning of a speech are best remembered. The next best position is the end of the speech.

5. Draw upon some or all of the following sources of belief: One, a logical train of thought which draws the audience with you to a logical conclusion; two, if possible, identify your statements with established, axiomatic principles; three, draw heavily upon personal experience; four, if possible, cite persons of expert knowledge on the matter in hand; five, draw upon public opinion itself, since the opinion of a group brings considerable authority; six, draw upon the audience's desire for satisfaction and advantage.

At the "Mike"

For the potential radio speaker and radio program, Mr. Max Karl, education director of WCCO, gave the following suggestions:

1. Physicians who plan radio campaigns should stick to talks and avoid the extravaganza type of program.

2. There is obvious limitation of time so far as the broadcaster is concerned. The schedule is divided into 15-minute periods, and the hours between six and ten in the evening are sold. Ask for 15 minutes time and be prepared to fill it.

3. Try out your voice first to see if it will broadcast well. If not, find someone else to make your talk whose voice is better. Let the broadcaster, who knows what carries best over the air, decide whether or not your voice is good—don't believe the comments of friends. Some people sound alive on the air and most people don't. In many cases, however, the broadcaster may be able to help you project your personality on the microphone.

Talk to Two or Three

4. Your audience is vaster than you could ever hope to have in a public hall; nevertheless, you must address yourself to two or three people as if you were having an intimate living room conversation.

5. Dr. W. A. O'Brien's formula for a radio talk is good. He answers the following questions: first, what is it or what is the cause? Second, how does it affect you? Third, what do you do about it?

A sheet of excellent suggestions on the preparation of radio talks was passed to the county officers by Mr. Karl and a copy is available upon request at the State Office.

"WE MUST TELL THE AMERICAN PEOPLE"—Dr. Leland

Dr. R. G. Leland, director of the American Medical Association's Bureau of Medical Economics, was a guest speaker at the conference. As an official representative of the American Medical Association and as an acknowledged authority on all questions relating to the distribution of medical care in the United States, Dr. Leland's remarks are important. They are reproduced in part here:

The new national health program and its sponsors have implied that delivery of medical care is helter-skelter in the United States, that the American Medical Association has had no health program, that its members have not looked after the health of the people. Members of the American Medical Association have been held up to ridicule and much has been done to shake the confidence of the people in their physicians.

Atmosphere Surcharged

We enter upon discussion of the program in an atmosphere surcharged with tension and confusion of terms. New and sly meanings have been devised for old terms.

To the physicians, the term "Socialized Medicine" is an inclusive term, covering insurance medicine, coöperative medicine, and state medicine. Actually, socialized medicine has nothing to do with the treatment of the patient. It is concerned with a variety of methods of distribution of medical care, all of which are financed by groups rather than independent individuals.

Terms Confused

"State Medicine" refers solely to medicine that is provided directly by the state. The only example of state medicine in existence is Russia and, even there, state medicine is not complete.

"Public Medicine" refers solely to the medical care provided by the government for special groups such as the insane and the tuberculous for the protection of the entire population. This type of medicine has been actively supported by the organized medical profession since the first meeting of the American Medical Association in 1847.

"Sickness insurance" refers solely to the prepayment method of financing medical care for sickness. In a compulsory form, this type of financing has been carried on extensively in other countries. We are justified in examining it carefully when any proposal is made for establishing it in our own country since a study of comparative death rates shows definitely that something is lacking in those countries that is present here.

The "Medical Group" means, to physicians, an association of several physicians for the purpose of using facilities in common. The term "Group Medicine" is often used to mean compulsory pre-payment medicine in current discussions on the subject.

The term "Coöperative Medicine" is likewise used to mean voluntary sickness insurance or contract medicine. Actually, coöperatives start at buying wholesale and selling to members at retail. Medicine cannot be bought at retail and it is obvious that people who talk about cooperative medicine are using the term incorrectly.

Answer Is "No"

The President submitted the national health program to Congress with only one recommendation—that the Congress study it carefully (editor's note: the Wagner bill, introduced since Dr. Leland's visit to St. Paul, is analyzed in the March 11 issue of the *Journal of the American Medical Association*).

We are told, by backers of the program and many others, that 40 million Americans are not receiving medical care.

Are one-third of the people in your community deprived of care? The answer of any physician would be "No." We are told that 20,000,000 people are receiving an annual income of less than $800; that 42½ per cent of them are now on some form of government relief.

If the government has assumed responsibility for the necessities of life for these people, why is it that they, at least, are not getting adequate medical care?

Furthermore, 7 per cent of these people are receiving aid under the Social Security Act. Why was it not thought necessary to include a provision for medical care in the amount allowed under this act?

Need Recognized

Another 42 per cent are in the marginal class. The medical profession recognizes fully the need for assistance for this class. But we believe that aid to these people is a community responsibility and should be financed by local taxation.

We believe in expanding public health measures. We do NOT believe that public health departments should be forced into the private practice of medicine.

We believe, also, in the expansion of hospital facilities. But we find many hospitals, now, with vacant beds and it seems to us senseless to spend more money to duplicate existing hospitals. Instead, government money should be used where it is needed to save the private hospitals. New hospitals should be built only in communities where the need can be fully demonstrated.

Medicine is not opposed in principle to any part of the program except to the recommendation for compulsory sickness insurance. If an opportunity arises to present our position to the House Ways and Means Committee I am sure representatives of state associations will be allowed to appear if they choose. In the meantime, it is essential that we tell the American people our position.

Medicine's Program

We have always had a program for the improvement of medicine and medical care. We have elevated the standards of education and of hospitals. We have developed boards in the specialties, all directed toward providing better qualified physicians. We are as irked by slowness of advances in the distribution of services as anybody.

The thing that distresses medicine, now, is how to effect a more even distribution. We are working on the problem. County medical societies should make and operate a variety of plans with the approval of their state associations. Ours is not a policy of objection or obstruction, and we have no need to be ashamed. We recognize that there are places where it is difficult to carry medical and hospital care, where the population is less than one person per square mile and where special measures must be instituted to provide for the people.

We are not opposed, certainly, to any plan that will provide good medical care for all the people at prices the people can afford to pay. But quality is more important, by far, than quantity in the distribution of medical service. We are definitely opposed to any plan whatsoever that will lower the quality of medical care given the American people.

DO YOU HELP OR HINDER?

(Monthly Editorial Prepared by the Medical Advisory Committee)

For several years, your Medical Advisory Committee has been preaching the power of toleration and judgment in the attitude of one medical man toward another; that the Golden Rule is as applicable today as it was in the past, and that, if each of our members would attempt to place himself in the other man's place, so-called malpractice litigation would cease or at least be confined to a very small number of cases.

A careful perusal of the number of cases being brought against us at this time shows that the membership of the society is becoming of one mind. Maybe the danger of Socialized Medicine has had its influence. Each one of us knows that if Socialized Medicine or one of its ramifications is not to be foisted onto the medical profession and the sacred, confidential patient-doctor relationship is not to be lost, we must take a most tolerant attitude toward one another. There must be no split in our ranks, our thoughts must be the same, our work must be bettered, our associations with each other must be more friendly, and a general feeling of helpfulness and interdependence engendered in our ranks.

Most of the cases brought during the last year against our members have had no merit and were attempts to obtain money from an easy source to pay the past due obligations of the plaintiff. A small percentage had some merit and were or could be easily settled to the advantage of all parties concerned.

Published papers show that there is very little difference in the type of medical work in various parts of the state, rural or urban, and that the people in all parts of Minnesota are particularly fortunate in the high type of professional men with whom they have to deal.

Further, inter-professional meetings such as the one recently held in Saint Paul should build up a most wholesome feeling between the men practicing dentistry, medicine, and law. They argue well for the future of the professions and their better mutual understanding. Attendance at a meeting of this type may answer for you the question, "Do you help or hinder?"—B.J.B.

MINNESOTA STATE BOARD OF MEDICAL EXAMINERS

Report of Licensure Under Date of February 11, 1939

By Examination

Anderson, Hubert Louis, Saint Paul, Minnesota. University of Minnesota, Bachelor of Medicine, June 13, 1938.

Bickel, William Harold, Rochester, Minnesota. Northwestern University, Doctor of Medicine, March 18, 1936.

Bigler, Ivan Edward, Duluth, Minnesota. University of Minnesota, Bachelor of Medicine, June 13, 1938.

Dorton, Howard Ellsworth, Rochester, Minnesota. University of Illinois, Doctor of Medicine, July 1, 1937.

Eck, Raymond Livingston, Livingston, Montana. University of Minnesota, Doctor of Medicine, March 17, 1938.

Eisenstadt, William Sawyer, St. Paul, Minnesota. University of Minnesota, Bachelor of Medicine, March 17, 1938.

English, John Paul, Rochester, Minnesota. University of Pennsylvania, Doctor of Medicine, June 19, 1935.

Fiel, Charles Augustus, Jr., Rochester, Minnesota. Indiana University, Doctor of Medicine, June 15, 1936.

Fleming, Dean Stephen, Minneapolis, Minnesota. University of Minnesota, Doctor of Medicine, March 18, 1937.

Guthrie, Robert Fulmer, Rochester, Minnesota, Emory University, Doctor of Medicine, June 11, 1934.

Harley, Robison Dooling, Rochester, Minnesota. University of Pennsylvania, Doctor of Medicine, June 10, 1936.

Harper, Samuel Bowman, Rochester, Minnesota. University of Wisconsin, Doctor of Medicine, June 21, 1937.

Hedemark, Norman George, St. Paul, Minnesota. University of Minnesota, Bachelor of Medicine, June 13, 1938.

Hursh, Marion Douglas, Lake City, Minnesota. University of Minnesota, Doctor of Medicine, June 13, 1938.

Idstrom, Linneus G., Minneapolis, Minnesota. University of Minnesota, Bachelor of Medicine, June 13, 1938.

Johnson, Allen Gray, Duluth, Minnesota. University of Minnesota, Bachelor of Medicine, June 13, 1938.

Johnson, Karl Eugene, Pine River, Minnesota. University of Minnesota, Doctor of Medicine, June 13, 1938.

Kamish, Robert James, Minneapolis, Minnesota. University of Minnesota, Doctor of Medicine, June 13, 1938.

Keithahn, Elmer Edward, St. Paul, Minnesota. University of Minnesota, Bachelor of Medicine, June 13, 1938.

Little, Alexander Graham, Jr., Rochester, Minnesota. Johns Hopkins University, Doctor of Medicine, June 7, 1937.

Loken, Selmer Milo, Saint Paul, Minnesota. Rush Medical College, Doctor of Medicine, June 10, 1938.

Magnuson, Allen Einer, Saint Paul, Minnesota. University of Minnesota, Bachelor of Medicine, June 13, 1938.

McCallig, John J., Rochester, Minnesota. University of Oregon, Doctor of Medicine, May 31, 1937.

McHeffey, George Jerome, Rochester, Minnesota. University of Michigan, Doctor of Medicine, June 23, 1930.

Nachtigall, Henry Blum, Ely, Minnesota. University of Minnesota, Bachelor of Medicine, June 13, 1938.

Patton, William Burgamy, Rochester, Minnesota. Johns Hopkins University, Doctor of Medicine, June 11, 1935.

Pedersen, Roy Clarence, Duluth, Minnesota, University of Minnesota, Bachelor of Medicine, March 13, 1938.

Prunty, Francis Crandall, Rochester, Minnesota. Jefferson, Doctor of Medicine, June 5, 1931.

Rasmussen, Waldemar Curtis, Rochester, Minnesota. University of Minnesota, Doctor of Medicine, June 15, 1936.

Robinson, Francis Joseph, Rochester, Minnesota. Northwestern University, Doctor of Medicine, June 13, 1936.

Scheifley, Charles Holland, Rochester, Minnesota. University of Minnesota, Bachelor of Medicine, June 14, 1937.

Sealy, William Burgess, Rochester, Minnesota. University of Texas, Doctor of Medicine, May 31, 1934.

Strem, Edward Louis, St. Paul, Minnesota. University of Minnesota, Bachelor of Medicine, June 13, 1938.

Svien, Hendrik J., Rochester, Minnesota. University of Minnesota, Doctor of Medicine, June 13, 1938.

Weaver, Paul Henry, Minneapolis, Minnesota. Ohio State University, Doctor of Medicine, June 13, 1938.

Williams, John Arthur, St. Paul, Minnesota. University of Minnesota, Bachelor of Medicine, June 13, 1938.

Wilson, Ira Herman, Rochester, Minnesota. University of Minnesota, Doctor of Medicine, December 19, 1935.

Woods, Robert Max, Rochester, Minnesota. Marquette University, Doctor of Medicine, June 15, 1938.

Yugend, Sidney Frederick, St. Paul, Minnesota. University of Minnesota, Doctor of Medicine, June 13, 1938.

By Reciprocity

Fishback, Charles Franklin, Minneapolis, Minnesota. Northwestern University, Doctor of Medicine, June 3, 1933.

Fleming, Ralph Gibson, Rochester, Minnesota. University of Pennsylvania, Doctor of Medicine, June 10, 1936.

Hyslop, Leland Francis, Wisconsin. Northwestern University, Doctor of Medicine, June 15, 1925.

Meriwether, Lodwick Sterritt, Rochester, Minnesota. University of Virginia, Doctor of Medicine, June 16, 1931.

Polan, Charles Gabriel, Minneapolis, Minnesota. Rush Medical College, Doctor of Medicine, June 16, 1936.

Rein, Walter John, Minneapolis, Minnesota. University of Wisconsin, Doctor of Medicine, June 24, 1935.

National Board

Lowry, Elizabeth C., Minneapolis, Minnesota. Cornell University, Doctor of Medicine, June 6, 1935.

Lowry, Thomas, Minneapolis, Minnesota. Cornell University, Doctor of Medicine, June 6, 1935.

Phillips, Richard Betts, Rochester, Minnesota. University of Edinburgh, Doctor of Medicine, December 15, 1933.

Wilson, William Hildebrand, Rochester, Minnesota. Northwestern University, Doctor of Medicine, June 11, 1938.

Minneapolis Physician Convicted of Manslaughter

Re: State of Minnesota vs. George F. Lemke.

On February 25, 1939, a jury in the District Court of Hennepin County returned a verdict of guilty against Dr. George F. Lemke, who formerly maintained offices at 512 Pence Building, Minneapolis. Dr. Lemke was charged with manslaughter in the first degree following the death, on December 10, 1938, of a 22-year-old Saint Paul girl. The indictment against Dr. Lemke charged him with the death of the girl following a criminal abortion.

On March 3, 1939, Judge W. W. Bardwell sentenced Dr. Lemke to a term of five to tweny years in prison in connection with this case. Dr. Lemke's lawyer announced that an appeal would be taken and the Court granted a stay of thirty days in which to perfect the appeal. Dr. Lemke's license, as a physician and surgeon, was revoked by the Minnesota State Board of Medical Examiners on February 11, 1939, following a hearing held before the Medical Board as the result of the death of this girl.

The case was well handled for the State of Minnesota by W. G. Compton, Peter S. Neilson and Howard T. Van Lear, Assistant County Attorneys.

In Memoriam

Andrew S. Backus
1881-1939

DR. ANDREW STEPHEN BACKUS died at St. Paul, January 20, 1939, at the age of fifty-seven.

Dr. Backus was born September 22, 1881, at Tyrconnel, Ontario, Canada, of Scotch and Irish lineage. His ancestors settled in that vicinity in 1809 on land purchased from Colonel Talbot, which is still occupied by some of their descendants.

He entered the medical college of Toronto University at the same time as an older and younger brother, and was graduated in 1905. Receiving the degrees of M.D., C.M., and F.T.M.C. upon graduation, he divided a year's internship between St. Michael's Hospital, Toronto, and Riverside Hospital at Buffalo, New York. He then went to San Francisco, California, and was ship surgeon on the S. S. San Jose, going to Panama, returning after the San Francisco earthquake.

Dr. Backus then went back to Toronto, Canada, and was married on November 14, 1906, to C. V. Maude Brown. Following his marriage, he went to North Dakota to practice and remained there until November 14, 1923, when he moved to Saint Paul, where he continued to practice until his death.

Dr. Backus was a member of Ramsey County Medical Society, and the Minnesota State Medical Association, and a staff member of Miday Hospital.

He was surgeon for the American Radiator Company from the opening until the closing of the Saint Paul plant in 1930. For several years, he was Deputy Coroner for the city of Saint Paul. He belonged to Hamline Methodist Church where he had served upon the finance board.

Dr. Backus was one of the organizers of the Como Golf Club, served as one of its officers, and was honorary vice president at his death. He was a member of the National Congress of Parents and Teachers.

He was also a member in good standing of the following fraternal organizations: Midway Lodge No. 185, A.F. and A.M., Minnesota Chapter No. 1, Royal Arch Masons, Minnesota Consistory, a member of Osman Temple Shrine, and Hamline Chapter No. 228, O.E.S. He had served for five years as trustee of B.P.O. Elks Lodge No. 59. He was also Trustee of Loyal Order of Moose No. 40 for six years.

In his obstetric practice, he never lost a mother though for seventeen years these cases were taken care of in North Dakota farm homes.

Dr. Backus was a friend, as well as a physician to his patients. He was honorable in his profession, kind, courteous, and sincere to everyone. He will truly be missed.

He is survived by his wife, and one brother, John Edward, of Ontario, Canada.

OF GENERAL INTEREST

On the evening of March 1, Dr. Irvine McQuarrie, Professor and Head of the Department of Pediatrics of the University of Minnesota Medical School, lectured before the Montreal Neurological Society at McGill University, Canada. The subject of his discourse was "Physico-chemical Studies on the Mechanism of Convulsive Phenomena."

* * *

Dr. E. O. Enroth, associate of Dr. E. R. Sterner, White Bear, Minnesota, for the past year and one-half, has taken over the entire practice in this community. Dr. Sterner, who has been dividing his time between his Saint Paul and White Bear offices, will now give full time to his Saint Paul practice.

* * *

On March 15, Dr. Richard F. Herbst, formerly of Minneapolis, assumed the practice at Hawley, Minnesota, of the late Dr. Martin C. Bergheim. Assisting Dr. Herbst is Mrs. Herbst, a graduate nurse of Saint Mary's Hospital, Minneapolis.

* * *

With Dr. E. F. McElmeel, of Pipestone, speaking on pneumonia and common colds, the women's organizations of Ihlen, Minnesota, on February 23, initiated the first in a planned series of medical discussions. Future discussions will bring to Ihlen other physicians from the surrounding districts.

* * *

Dr. P. S. Hench, of Rochester, Minnesota, addressed the New York Academy of Medicine on March 2, and the Southern California Medical Association on March 15. Mrs. Hench, with the children, and her mother, Mrs. J. H. Kahler, left about March 1, for California, where Dr. Hench joined them after returning from his speaking engagement in the East.

* * *

Dr. John P. Darling, Rochester, who was seriously injured in an automobile accident in January, is now in Florida, completing his convalescence.

* * *

Shortly after the first of March, Dr. and Mrs. L. F. Wasson moved to Osakis, Minnesota, where Dr. Wasson joined Dr. E. Haberman in the practice of medicine. Dr. Wasson formerly practiced in Chisago City.

* * *

At the meeting of the medical history society, Cos Cnidos, held in the Minneapolis Club, March 15, 1939, Dr. Arthur E. Hertzler, of Halstead, Kansas, gave reminiscences of his early days in the practice of medicine and presented some of his ideas regarding thyroid disease. Dr. S. Marx White was elected president of the society to succeed Dr. John Armstrong. Miss Jean E. Hirsch was reëlected secretary-treasurer.

Dr. G. B. Eusterman and Dr. W. C. Alvarez, of Rochester, have been honored by being elected corresponding members of the Societé de Gastro-enterologie de Paris. The society met December 12, 1938.

* * *

President of the Todd County Medical Association, Dr. W. W. Will, of Bertha, Minnesota, presided at a dinner meeting of the organization on February 23. The program of the evening included a discussion of fractures of the hip, by Dr. A. W. Ide, chief surgeon of the N. P. B. A. Hospital, Saint Paul, and a paper on cancer of the large intestine, by Dr. W. J. Lund of Staples.

* * *

Dr. Howard Burchell, a fellow of the Mayo Foundation, left March 7 for London, where he will study for five months. Dr. Burchell was guest of honor at a dinner given by Dr. George Pollock, of Rochester, Minnesota, on the Saturday evening preceding the latter's departure.

* * *

At the annual meeting and post graduate course of the Alumni Association of the University of Oregon Medical School, held the first Monday and Tuesday of March, Dr. G. B. Eusterman, of Rochester, delivered three lectures and conducted a roundtable discussion. On Monday, March 13, he addressed the Columbia Medical Society of Columbia, South Carolina.

* * *

Dr. Paul Rick, who has been physician and surgeon in the community of Le Center, Minnesota, for the past two years, recently opened offices in Saint Paul at 966 Arcade Street.

* * *

Dr. W. R. Lovelace, Fellow in surgery of the Mayo Foundation, will go to Europe in April for two months' study, as a result of his having received the J. William White Scholarship. Contributory to his receiving this award was his part in developing an oxygen mask for the comfort of aviators flying at high altitudes. He collaborated in this work with Dr. W. M. Boothby and Dr. H. A. Bulbulian.

* * *

The Annual Harold S. Boquist Lecture at the University of Minnesota Medical School will be given by Dr. Henry C. Sweany, Medical Director of Research, Chicago Tuberculosis Sanatorium, on Tuesday, April 4, 1939. Dr. Sweany's subject will be "The Study of the Pathogenesis of Tuberculosis by Correlating Age and Morphology of Primary Tubercles."

* * *

The Eastern Clinic of Fergus Falls has recently moved into its new commodious clinic building at 106 South Union Avenue. The Clinic's personnel consists of Dr. C. O. Estrem, Dr. E. A. Heiberg, Dr. G. J. Mouritsen, and Dr. C. J. Lund.

REPORTS and ANNOUNCEMENTS

MEDICAL BROADCAST FOR APRIL

The Minnesota State Medical Association Morning Health Service

The Minnesota State Medical Association broadcasts weekly at 11:00 o'clock every Saturday morning over Station WCCO, Minneapolis (810 kilocycles or 370.2 meters) and Station WLB, University of Minnesota (760 kilocycles or 395 meters).

Speaker: William A. O'Brien, M.D., Associate Professor of Pathology and Preventive Medicine, Medical School, University of Minnesota. The program for the month will be as follows:

April 1—Cause of Cancer
April 8—Cancer in Women
April 15—Cancer in Men
April 22—Early Diagnosis of Tuberculosis
April 29—Cancer of the Head and Neck

AMERICAN BOARD OF INTERNAL MEDICINE, INC.

Written examinations for certification by the American Board of Internal Medicine will be held in various sections of the United States on the third Monday in October and the third Monday in February.

Formal application must be received by the Secretary before August 20, 1939, for the October 16, 1939, examination, and on or before January 1 for the February 19, 1940, examination.

Application forms may be obtained from Dr. William S. Middleton, Secretary-Treasurer, 1301 University Avenue, Madison, Wisconsin, U. S. A.

POSTGRADUATE COURSE FOR PHYSICIANS IN OBSTETRICS AND PEDIATRICS

Beginning Wednesday, April 26, and continuing for five consecutive Wednesdays, the third annual series of the Postgraduate Course for Physicians in Obstetrics and Pediatrics will be presented in ten centers of the state. This course is sponsored jointly by the Minnesota State Medical Association, the Medical School of the State University, and the Minnesota Department of Health. It is financed by Maternal and Child Health funds coming to the Minnesota Department of Health under the provisions of the Social Security Act. The dates and places for the meetings are as follows:

April 26—Pine City
Winona
May 3—Fergus Falls
Little Falls
May 10—Willmar
Virginia
May 17—Worthington
Grand Rapids
May 24—Albert Lea
Crookston

The meetings will be conducted in the same manner as last year, which proved so acceptable to the practicing physicians. There will be one full day meeting in each center, beginning promptly at 8 o'clock in the morning, and composed of eight lecture and discussion periods—four each on obstetrics and pediatrics. Further information covering the details of arrangements will be mailed to the physicians in the near future.

STATE MEETING

The introduction of two series of Round Table luncheons constitutes one of the most interesting innovations scheduled for the Minnesota State Medical Association's 86th Annual Meeting to be held at the Minneapolis Auditorium, May 31, June 1 and 2.

Similar luncheon meetings are an established and very popular feature of the meetings of the State Medical Society of Wisconsin. If they are well received in Minneapolis, they may become a regular part of future meetings in Minnesota.

There will be ten of these luncheons on Wednesday, May 31, and ten on Thursday, each on a different subject, with leaders picked from the visiting speakers and from Minnesota leaders among the specialties. Only 20 tickets will be sold for each luncheon so that discussion groups may be kept small. No formal programs will be arranged.

The list of subjects will be sent to each member. Those who wish to attend will be required to buy their tickets in advance and send in first, second, and third choices in case registrations should be filled. The luncheons will be held in the Curtis Hotel, which has been selected as hotel headquarters for the meeting.

A distinguished scientific program has been arranged for the first two days of the meeting, with Dr. Andrew C. Ivy of Northwestern University, Dr. Thomas Francis, Jr., of New York University, and Dr. W. Edward Chamberlain of Temple University among the guest speakers.

A fracture demonstration hour conducted by Dr. O. W. Yoerg of Minneapolis, Dr. Victor Hauser of St. Paul and Dr. Henry Meyerding of Rochester is an unusual feature of the first morning's program. An extensive fracture exhibit under auspices of the Committee on Fractures rounds out an unusual program section on fractures.

Among other demonstrations of immediate especial current interest will be three from the Department of Surgery of the University of Minnesota, including a demonstration on blood transfusion, on the treatment of surgical shock and also the treatment of intestinal obstruction and the uses of nasal suction. Dr. W. R. Lovelace and his associates, of Rochester, will be there, also, to demonstrate their oxygen masks for high altitude flying. Demonstrations, exhibits and a carefully selected group of motion pictures will occupy two 45-minute program recesses each day.

The annual banquet is scheduled for Thursday night, June 1, at the Curtis, with Governor Harold E. Stassen as principal speaker.

The Friday program will be devoted exclusively to a Conference on Medical Problems in which dentists, pharmacists, nurses, social welfare workers and hospital administrators will be invited to participate. Among the speakers already scheduled for this conference are Dr. F. W. Jackson, Winnipeg, Deputy Minister of Health of Manitoba; Mr. J. G. Crownhart of Madison, secretary of the State Medical Society of Wisconsin; Attorney General J. A. A. Burnquist and Senator Henrik Shipstead. Final announcement of speakers and program for this session will await legislative developments in Washington so that its subject matter may be pertinent to the current situation.

Five thousand physicians from Minnesota, Wisconsin, Iowa, the Dakotas, Montana and the nearer provinces of Canada will be invited to the scientific sessions. They will be joined by members of allied professions from all over the state for the Friday meeting.

MINNEAPOLIS SURGICAL SOCIETY

At the regular monthly meeting of the Minneapolis Surgical Society, held in the Minneapolis Athletic Club on the evening of Thursday, March 2, Dr. Willard B. White was elected president for the ensuing year, Dr. L. Haynes Fowler, vice president and Dr. H. M. Lee, member of the executive council. Dr. Harvey Nelson carries over as secretary-treasurer, having been reëlected for three years, last year. Dr. George R. Dunn, president, was president last year.

WASHINGTON COUNTY

Members of the Washington County Medical Society, at their meeting March 14, heard Dr. H. E. Richardson, of Saint Paul, discuss, at length, "Some Heart Conditions." His talks proved very instructive. He carefully explained newer methods of diagnosis, especially emphasizing electrocardiography as a great help in obscure heart conditions, whereby earlier recognition of these are possible, and better end-results in treatment may be obtained. He advocated complete rest, and the judicious and careful use of drugs as indicated.

WINONA AND WABASHA COUNTY JOINT MEETING

The eighth annual joint meeting of the Winona and Wabasha County Medical Societies, and the fourteenth annual dinner tendered by the Buena Vista Sanatorium Commission to the physicians of the counties, was held at the Sanatorium, Wabasha, Monday evening, March 13. There were thirty-two in attendance. The program was arranged by Dr. Russell H. Frost, superintendent of the Sanatorium, with Dr. R. L. Page of St. Charles, president of the Winona County Society, acting as toastmaster.

Speakers and subjects were as follows:

Dr. George A. Earl, St. Paul, president of the Minnesota State Medical Association—"Carcinoma of the Gastro-intestinal Tract."

Dr. Edward T. Evans, Minneapolis—"Common Orthopædic Conditions of the Foot, Knee, and Hip."

Dr. Lewis I. Younger, Winona, read on its fiftieth anniversary, a paper on "The Contagiousness of Tuberculosis," originally presented in 1889 by the late Dr. Donald B. Pritchard of Winona. Discussion by Dr. Russell H. Frost, superintendent of the Buena Vista Sanatorium.

Dr. Benjamin B. Souster, St. Paul, showed a movie illustrating the "Mechanism of the Heart Beat and Electrocardiography."

In addition, Dr. Earl, president; Mr. R. R. Rosell, executive secretary, and Dr. Souster, secretary, discussed the problems of the Minnesota State Medical Association and present-day trends in medical practice.

AMERICAN ASSOCIATION OF INDUSTRIAL PHYSICIANS AND SURGEONS

The 24th annual meeting of the American Association of Industrial Physicians and Surgeons with the American Conference on Occupational Diseases and Industrial Hygiene will be held at the Hotel Statler, Cleveland, Ohio, June 5, 6, 7 and 8, 1939. A program of timely interest and importance will be presented by speakers of outstanding experience in all of the medical and engineering problems involved in industrial health. A cordial invitation is extended to all whose interests bring them in contact with these problems. Information regarding hotel accommodations, etc., may be obtained from A. G. Park, Convention Manager, 540 North Michigan Avenue, Chicago.

AMERICAN ASSOCIATION ON MENTAL DEFECT

The 63rd annual convention of the American Association on Mental Defect will be held at the Palmer House in Chicago, Illinois, from May 3 to 6, inclusive.

Dr. C. Stanley Raymond, Wrentham State School, Wrentham, Massachusetts, is chairman of the Public Relations Committee.

SCOTT-CARVER SOCIETY

On March 14, 1939, the Scott-Carver Medical Society met at Mudcura Sanitarium. Dr. Edgar Bedford, Minneapolis, spoke on "The Clinical Aspects of Gallbladder Disease." Dr. Ames Naslund spoke on "X-ray Diagnosis in Gallbladder Pathology."

The Society was also recently addressed by Dr. Carl Rice, Minneapolis, who spoke on "Indications for Surgery of the Thyroid Gland"; and Dr. Chauncey Borman, Minneapolis, who spoke on X-ray Measurements of the Female Pelvis."

WOMEN'S AUXILIARY

MRS. W. B. ROBERTS, Minneapolis, *President*
MRS. E. V. GOLTZ, 2259 Summit Avenue, Saint Paul, *Publicity Chairman*

Hennepin County

Members of the Woman's Auxiliary of the Hennepin County Medical Society held their March meeting Friday, March 10, in the lounge in the Medical Arts Building, Minneapolis. The meeting was postponed from Friday, March 3, due to the elevator strike. After the regular business meeting the group heard Dr. Brown of the Child Guidance Clinic of the Minneapolis Public Schools speak on "Mental Health" which was a most interesting discussion. Tea followed with a social hour. Mrs. W. B. Roberts and Mrs. C. E. Willcutt poured. Mrs. L. R. Boies was the social chairman.

Hennepin County members are busy planning their annual card party which is held each year on Easter Monday, the proceeds being used for philanthropic work. This year there will be nine different parties at various homes with one party in the main lounge in the Medical Arts building. These parties will be in various districts of the city, and the following members will be hostesses: Mmes. O. J. Campbell, L. O. Doyle, R. M. Ericson, J. C. Hultkrans, R. T. Knight, C. M. Larson, F. B. Mach, Carl O. Rice and C. W. Waldron. Mrs. C. E. Willcutt is the general chairman and Mrs. H. B. Hannah is co-chairman.

Plans are nearly completed, now, for the annual convention to be held in Minneapolis in May and the Hennepin County members are looking forward to a large registration. Mrs. J. S. Reynolds will be the chairman for this event.

Several members of the State Auxiliary were recent guests at a meeting held in the Woman's Club, Minneapolis, when women from various parts of the state who are serving on the Minnesota Committee on Woman's Participation in the New York World's Fair were guests of Mrs. John Dalrymple. Those attending the luncheon included Mrs. J. A. Thabes of Brainerd and Mrs. A. A. Passer of Olivia.

A baby son was born, February 25, to Dr. and Mrs. Leo Fink of Minneapolis. Mrs. Fink is the publicity chairman for the Hennepin County Auxiliary.

A number of Hennepin County members have enjoyed vacations in the south this winter, including Dr. and Mrs. R. R. Cranmer, Dr. and Mrs. Martin Nordland, Dr. and Mrs. J. C. Davis, Dr. and Mrs. J. S. Reynolds, and Dr. and Mrs. J. H. Simons.

* * *

West Central

Our State President, Mrs. W. B. Roberts, attended the March meeting of the West Central group which was held March 8 in Morris, Minn., with the president, Mrs. I. L. Oliver of Graceville, presiding. It was a joint meeting with a dinner at the hotel after which members of the Auxiliary held their business meeting. Mrs. Roberts was the house guest of Mrs. Charles Bolsta of Ortonville who is a member of the State Advisory committee.

* * *

Washington County

March 14, members of the Washington County Auxiliary held a meeting at the home of Mrs. R. J. Josewski in Stillwater. Nine members were present and Mrs. W. B. Roberts motored to Stillwater for the event. During the meeting, Mrs. Josewski received a package from the Hygeia department of the American Medical Association, containing a statute, a gift in appreciation of her services in the Hygeia campaign. Minnesota can be proud of the results of this contest for Washington County won sixth place and Park Region fifth place in the entire United States, which gives Minnesota two places out of the ten.

After the business meeting, Mrs. Josewski served a delicious supper.

Recent Developments in the Treatment of Undulant Fever

The increased recognition and incidence of undulant fever has fortunately been associated with new and improved methods of treating this disease, in both its acute and its chronic form. Vaccines have been employed for about ten years, in many instances with apparent success. Convalescent serum and transfusion with whole blood have also been reported as sometimes successful in the treatment of the disease. During the past year favorable reports of the treatment of undulant fever with sulfanilamide or its compounds have rapidly accumulated. From the information available it seems likely that sulfanilamide in rather large doses is necessary but that at least in some resistant cases the results are comparable, if not superior, to any other form of treatment of undulant fever thus far proposed. Successful results have also been claimed for physically induced hyperpyrexia treatments, and the intravenous administration of neoarsphenamine. Although a decision as to the value of any method of treatment in undulant fever is difficult because of the alternation of febrile periods and afebrile pauses, the available methods of therapy are such as to allow the disease to be met with a much more powerful therapeutic armamentarium than existed a few years ago. (J.A.M.A., Nov. 5, 1938, p. 1769.)

PROCEEDINGS OF THE MINNESOTA ACADEMY OF MEDICINE

Meeting of February 8, 1939

The regular monthly meeting of the Minnesota Academy of Medicine was held at the Town and Country Club on Wednesday evening, February 8, 1939. Dinner was served at 7 o'clock and the meeting was called to order at 8:10 p. m. by the president, Dr. Carl B. Drake.

There were forty-eight members present.

Minutes of the January meeting were read and approved.

The secretary read two proposed amendments to the Constitution which will be published in the next program and voted upon at the March meeting.

The scientific program followed.

TROPICAL AND NONTROPICAL SPRUE (CHRONIC IDIOPATHIC STEATORRHEA) THEIR PROBABLE INTERRELATIONSHIP*

Albert M. Snell, M.D.

Rochester, Minnesota

Dr. Albert M. Snell, of Rochester, read his inaugural thesis on the above subject. Lantern slides were shown.

Abstract

Sprue has been defined by Frederic Hanes as "a chronic deficiency state with a marked tendency to remissions and relapses characterized, when fully developed, by glossitis and stomatitis, anorexia, gastrointestinal indigestion, by the passage of large, fatty, frothy, foul-smelling stools, by great loss of weight, generalized muscular wasting and, in adults and some children, by macrocytic-hyperchromic anemia. It responds promptly to liver therapy."

The disease was formerly supposed to be confined to the tropics, but in recent years a considerable number of cases have been reported from temperate climates. At the Mayo Clinic, we have had an opportunity of seeing a group of "imported" cases of tropical sprue and have compared the signs and symptoms present in these cases with those in cases in which the disease was acquired in northern latitudes. Records of eighteen patients with non-tropical sprue have been examined and in each case the clinical picture and the response to treatment with liver extract was identical with that seen in cases of tropical sprue.

We also have records of fourteen patients whose condition had no bearing on tropical residence and who presented the characteristic signs of sprue (steatorrhea, macrocytic anemia and glossitis) and in addition a variety of metabolic and nutritional disturbances, including tetany, osteoporosis, growth defects, hypoproteinemia with edema, pellagra, hemorrhagic states, pigmentation of the skin, subacute combined degeneration and other less common nutritional disturbances. Hypovitaminosis D is a conspicuous feature. These cases correspond to a condition which has been described in the English and Scandinavian literature as "idiopathic steatorrhea." They appear to represent the end results of long-continued intestinal dysfunction with failure of absorption of the necessary minerals and vitamins. Certain of the patients responded in satisfactory manner to parenteral administration of liver extract although large doses and persistent treatment were required.

Observations of individual cases from both groups over long periods of time bring out some interesting points. Neither sprue nor "idiopathic steatorrhea" is a static condition and in certain cases the basic condition, that is, sprue, has been seen gradually to give rise to multiple symptoms of deficiency related to loss of minerals, vitamins and essential foodstuffs. In these cases, seen in the stage of transition, treatment with liver extract may still be extraordinarily effective. The difference between sprue and steatorrhea appear on the whole to represent different stages in the breakdown of the absorptive function of the small intestine, but the two conditions do not differ fundamentally. The distinctions which have been made between them in the past appear to be largely artificial and the intractable nature of so-called "idiopathic steatorrhea" appears to be largely a matter of delayed diagnosis and inadequate treatment. The syndrome of sprue and its immediate and late sequelæ are not uncommonly encountered in temperate climates and their earlier recognition and treatment would largely eliminate those cases which now present the advanced and intractable types of metabolic and nutritional disturbances.

Nontropical sprue should be diagnosed without difficulty if its existence is borne in mind. The principal conditions to be distinguished from it are gastrojejunocolic fistula, mesenteric lymphadenopathy and various types of pancreatic disease.

Discussion

Dr. Irvine McQuarrie (U. of M.): This is almost identical with celiac disease we see in children in some of our clinics. It is not very common but practically every children's clinic has a few cases. We recognize two rather distinct forms which are superficially alike. One occurs under two or three years of age. The mortality is very high in this group. In them, there is chronic cystic pancreatitis associated with chronic fibrosis of the lungs. Then there is another group in which there is no demonstrable pancreatitis but the stools have the same gross appearance. In such children in either group the dietary deficiencies most frequently observed are in Vitamins A, D, and sometimes C, and possibly B. I cannot recall having seen cases showing hemorrhagic tendencies, which would indicate absence of K, but they may occur. I can recall having seen two cases of celiac disease with xerophthalmia and rickets. One group of cases gets well on a high-protein, high-vitamin diet, while the other group responds unsatisfactorily to all forms of therapy. These latter cases with cystic pancreatitis have more neutral fat in the stools than do the genuine celiac cases. In these, soaps and free fatty acids predominate in the stool. There is probably still another group of celiac cases which fit into the sprue series.

---

*Division of Medicine, The Mayo Clinic.

I would like to congratulate Dr. Snell on the excellent presentation of this subject. I often wish that our students and young clinicians at the University could emulate this type of presentation.

I would like to ask Dr. Snell to express his views regarding the etiology of nontropical sprue or to make a brief evaluation of the current theories concerning its etiology. It was once thought that monilia or some organism of that nature has made sprue more frequent in the tropics than in the temperate zones.

Dr. Snell (in closing): I am grateful to Dr. McQuarrie for this discussion, and particularly for his comments on the relation of pancreatic atrophy to certain forms of celiac disease. In the adult, chronic pancreatitis with destruction of the acinar tissue of the organ may simulate sprue closely. If a fatty liver which may develop in the course of pancreatic atrophy makes its contribution to the clinical picture, the diagnostic difficulties are multiplied. The case reported by Norris, Beard and Gerber in the Archives of Pathology, December, 1938, is an example of this problem.

The principal reliance in distinguishing pancreatic disease from sprue is placed on the glucose tolerance test; the rises in blood sugar are characteristically of diabetic type in pancreatic disease, while in sprue a very small rise (20 mg. per cent or less) is the rule. A study of the enzymatic activity of the duodenal content is also of diagnostic value, since the pancreatic enzymes are only slightly reduced in sprue.

The etiology of sprue is still undecided. It is a deficiency disease in somewhat the same sense as is pernicious anemia. In its uncomplicated form, it responds in a specific manner to parenteral administration of liver extract; when multiple symptoms of deficiency appear, liver extract will correct the anemia of the disease but it does not necessarily control the fatty diarrhea or cure the intestinal dysfunction. The latter factor, that is, loss of the absorptive function of the small intestine, is the fundamental lesion in sprue although a constant pathologic picture has not been demonstrated. One, therefore, must postulate a physiologic failure of some sort. A constitutional factor has been invoked and Verzar has even attributed the intestinal dysfunction to a specific failure of cortical adrenal function. Such a breakdown does actually occur as a terminal feature in the adrenalectomized animal and, curiously enough, sprue itself may respond to some extent at least to cortical hormone. Many additional data are needed to clarify this point and, for the present, sprue and its related syndromes are best regarded as deficiency diseases. Monilia, incidentally, has nothing to do with the condition. Why sprue is more common in certain endemic areas in the tropics than elsewhere never has been explained satisfactorily; until it is known why this is so, further extension and revision of ideas concerning etiology are to be expected.

PARALARYNGEAL ATHEROMA

Arnold Schwyzer, M.D.

Saint Paul

The first case I want to report is of interest only as to its etiology. It was a simple little atheroma, but its location proved it to be due to an embryological remnant of a gill cleft. The gill clefts are the depressions, as seen from the outside, between the branchial arches which form the sides of the neck. Seen from the inside there are also depressions between these branchial arches; they are called the pharyngeal pouches. Ectoderm and the entoderm of the foregut come into direct contact between the branchial arches. There is no mesenchyme separating these two fine epithelial layers, and perforation may, therefore, occur very easily as it does normally in fishes. Embryogenic remnants are seen quite frequently on the neck, due either to persistent ectodermal or entodermal cells. We then have congenital cysts of fistulæ. If the remnant is derived from the pharyngeal pouch, the epithelium is cylindrical and it is resting on lymphoid tissue; while ectodermal formations are lined with a stratified pavement cell epithelium. The second and third branchial arches grow much larger than the lower ones and overlap the latter downward. By this, an ectodermal pocket is formed called the cervical sinus. An enclosed epidermal remnant growing into a macroscopic atheroma may thus be due to a remnant of a branchial cleft or of the cervical sinus.

The atheroma which we encountered four weeks ago was not one of those very common atheromata which, in the upper portion of the neck, are quite commonly found in the midline and represent superficial formations. The cystic mass under discussion was deep-seated laterally below the submaxillary gland. It was reached only by cutting the sternohyoid and omohyoid muscles near the hyoid horn. Its size was that of a large cherry and it rested to the side of the larynx on the sheath of the large vessels. It was, therefore, a remnant of a gill cleft. (Slides shown.) The cervical sinus in the fully-formed child opens, if it is persistent, low down on the neck near the head of the clavicle.

MESENTERIC LYMPHADENITIS

Case Reports

Arnold Schwyzer, M.D.

Saint Paul, Minnesota

Dr. Schwyzer reported two cases of mesenteric lymphadenitis, as follows:

Case 1.—Miss L. B., twenty years old, had an appendectomy for an acute appendicitis. After the operation she was free from her previous abdominal pain for about a month and then it reappeared as a dull pain after meals. Six months after the removal of the appendix the condition became acute one night. The pain was severe and she vomited several times. In the morning she was taken to the hospital. The tenderness was principally in the epigastrium and a perforating ulcer seemed the most plausible diagnosis. After watching her for a couple of hours, during which time other work had to be done, the tenderness and pulse, which at first had improved a trifle, were not enough better to wait longer. An incision was made a little to the right of the midline over the upper abdomen. The stomach, duodenum, and gallbladder were normal. The hand was introduced into the lower abdomen and found in the pelvis a stiff ballooned bowel loop of dark blue color. It was strangulated, as my sketch (Fig. 1) shows, by a rather thick cord which ran from the root of the meso-ileum over to the mesosigmoid. Between this firm band and the posterior abdominal wall, the bowel loop had slipped down toward the pelvis. On manipulation the attachment of the constricting cord broke away from a roundish mass of the size of a small walnut at the root of the meso-ileum. The raw surface was grayish-reddish with some gray specks here and there. It was an enlarged infected and partly broken-down lymph node. The constricting band was cut away from the mesosigmoid; the bowel loop became less tense and of good color. What should be done with the broken-down lymph node? We figured that the infection was an old one because the drawing out of the adhesion must have taken a long period of peristaltic pulling and because there was no fibrin deposit or other sign of more recent inflammation. Excision was not desirable as it might stir up the old infection and some blood in the bed would readily become infected. We relied on the defensive power of the peritoneum if given proper chance by not damaging it. We laid the meso-ileum, which was directly above this raw surface, over it and closed the abdomen. Convalescence was smooth and the patient has remained symptom-free. She is now married and has had three children.

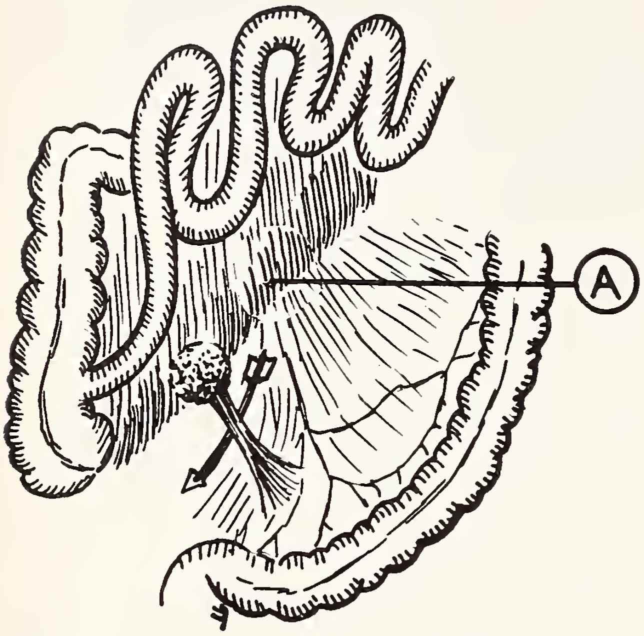

Fig. 1. Lymphadenitis with partial necrosis. Perilymphadenitis adhesion to meso-sigmoid, drawn out into cord under which a small bowel loop became strangulated. *A*, root of meso-ileum.

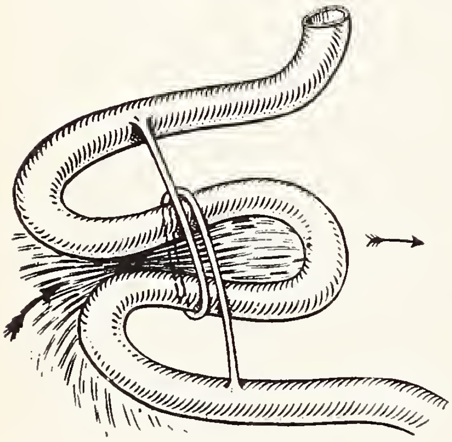

Fig. 2.

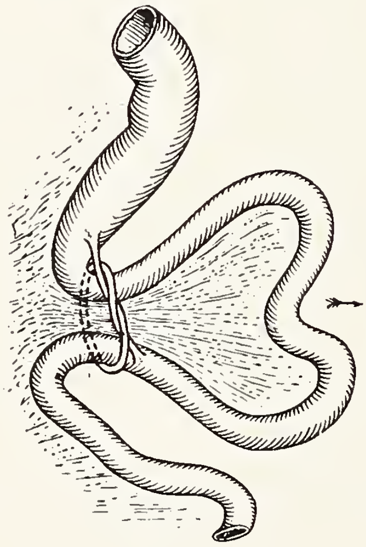

Fig. 3.

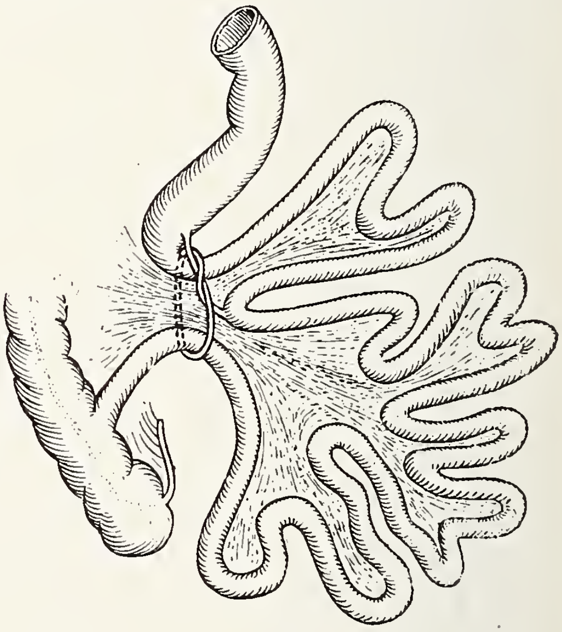

Fig. 4.

There were no other lymph nodes of enlarged size noticed and the microscopic examination of the end of the constricting cord, containing some of the lymph node tissue, showed no tuberculosis.

The most plausible explanation, in the absence of other findings, appears to be that at the time of the appendicitis there had existed an acute lymphangitis and a partial suppurative lymphadenitis in the gland under consideration. With the removal of the appendix, the infection gradually cooled off; the peritoneum had become agglutinated, walling off the focus and then gradually this adhesion, which had been quite bulky, was drawn out into a cord. But the cord was stretched only to a short length extending merely from the root of the meso-ileum to rather near the base of the mesocolon. Only the peristalsis of the colon caused any pulling and not for any great distance.

As a rule, such adhesions when greatly lengthened draw out into quite thin strings.

I may be forgiven for a slight digression in mentioning two extraordinary cases. In one, such a cord had strangulated practically the whole small intestine. It had formed of an adhesion near the root of the appendix. The whole ileum and most of the jejunum were black and enormously ballooned. These guts had to be watched for fully fifteen minutes while kept in warm pads, before we dared replace them. Fortunately, the patient made the grade.

When the adhesion is attached, at least at one end, to the small gut itself it may become stretched very much and a rather long thinned-out string may be the result. When I was still pathologist to the City and County Hospital I had an opportunity to make an autopsy on a very interesting case of this kind. (St. Paul Med. Jour., Feb., 1901.) The constricting band was 7.5 cm. long. It was attached at both ends to points on the ileum. By accident, a loop had formed by this cord and a small segment of ileum entered it. A true knot then was accomplished (Figs. 2, 3 and 4) when the gut with the lower attachment of the cord was pulled in through the ring. It appears that in these cases it is always the lower (efferent) segment which slips in further and further due to the peristaltic action of the entrapped gut. Imagine a rubber band around one end of a wet sausage skin which is now blown up. The end becomes stretched out and the rubber band has the tendency to be pushed off through the pulling action of the distension. By such pulling action, you see a long stretch of gut entered through the strangulating ring, and it is all from the lower side. In the same way, peristalsis at the afferent loop would tend to free the gut. The mesentery of a given segment of bowel is less bulky nearer the root, inasmuch as it measures 20 feet at the gut while its base is only 15 centimeters long. We find, therefore, a tendency of the constricting ring to slip toward the base of the mesentery while more and more gut enters the constricting ring. My sketch (Fig. 4), of course, is quite schematic; the strangulated gut measured 5 feet.

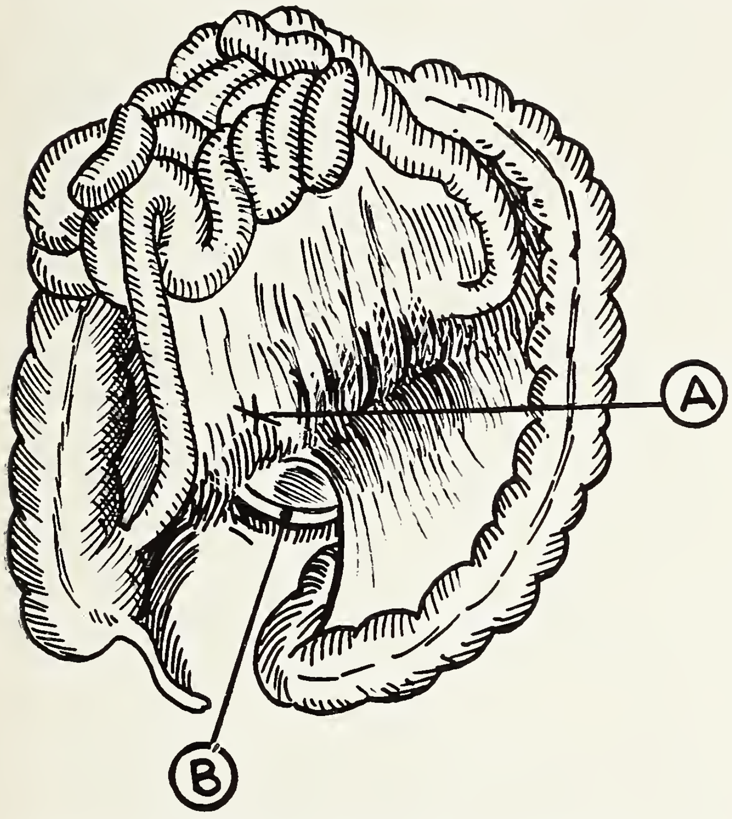

Fig. 5. Lymphadenitis putrid abscess of mesentery, acute appendicitis. *A,* location of abscess; *B,* promontory.

Case 2.—While the first case described was a late effect of a lymphadenitis of the base of the mesentery, the one to be discussed now is that of an acute condition of this kind. A woman, fifty-four years old, was admitted to St. Joseph's Hospital on the afternoon of December 27, 1938, as a case of acute appendicitis. Her history was not very clear. She had been more or less ill for two months and considered it "flu." She had been coughing for the last two weeks. On the evening of the day before entering the hospital she was seized with severe pain in the lower abdomen and took a laxative. She felt very sick and vomited frequently during the night and the morning.

The patient appeared very ill. The abdomen was a little bloated; tenderness existed in the right iliac and in the lower mid-abdomen. Palpation was, of course, very light but there was only moderate muscle defense on palpation at McBurney's point though the whole abdomen was somewhat rigid. Subjectively, the most pain was in the lower central abdominal region. The temperature was 100.2°, leukocytes 19,450, and the urine was practically normal. The acuteness of the picture did not allow of any delay and she was operated upon that same afternoon. In perfect anesthesia with spinocain, a gridiron incision, five centimeters long, was made a little below McBurney's point. The appendix was quite markedly reddened but there was no fibrin on it. It was removed. The palpation of the pelvis showed a normal condition. It was clear that this free, though red, appendix could not explain the severity of the onset and the tenderness of the mid-abdomen. The next move was to look for a possible trouble with a Meckel's diverticulum. Following the ileum upward from the cecum we noticed that the meso-ileum was short and thick. Replacing always the piece of gut examined, we worked up on the gut for a little over a foot when we encountered a foul abscess which the lifting of the gut had apparently broken. There was a strong coli odor. Immediately, the pus was caught in gauze and the pelvis protected. After mopping the parts dry, inspection showed that the abscess cavity had been about the size of a large plum and was located at the very root of the mesentery (Fig. 5). Drainage of this very foul, localized peritonitis had to be accomplished as much away from the free general peritoneal cavity as possible. A thin rubber tube and two collapsible rubber drains were placed so that their course from the abscess to the surface did not come into contact with the small guts, by laying the mesentery of the adjoining ileum over the drains and pulling the very large cecum mesially by a catgut stitch to the peritoneum of the anterior abdominal wall (Fig. 6). By keeping the patient strictly in the prone position for about five days, the postoperative course was rather smooth, though, of course, for the first days the discharge was profuse. Ten days after the operation the patient was up in a chair and she left the hospital on January 16.

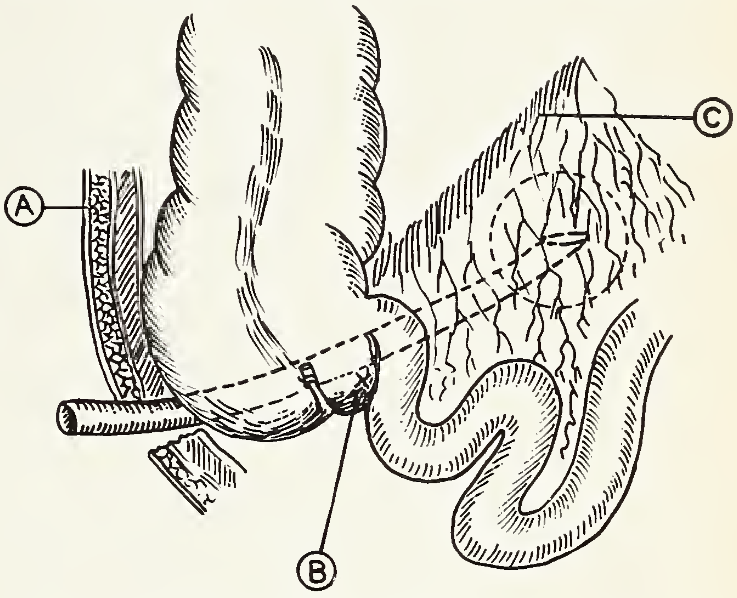

Fig. 6. Same as shown in Figure 5. *A,* abdominal wall; *B,* cecum fixed to anterior abdominal wall by catgut stitch, which pulls it over toward midline, thereby keeping the drainage tract away from the small bowel and free peritoneal cavity.

The favorable outcome was undoubtedly due to what amounted practically to an extraperitoneal course of the drainage tract and to the prolonged prone position to which the patient submitted without complaint.

What was the cause of this coli bacillus abscess? The appendix was not in any direct contact and was even a marked distance from it. The coli bacillus must have entered from somewhere on the mucosal surface of the gut. No other area except the appendix could be incriminated. The lymphatics of the appendix partly run up along the inner side of the cecum and partly toward the lymph nodes of the root of the meso-ileum, while some less-traveled roads lead, in women, toward the ovarian system.

The examination of the appendix under the microscope, definitely cleared the question as to the original source of infection. The pathologist's report (Dr. Maun) reads in part—"Lumen almost completely obliterated. About the vessels of the serosa are large numbers of inflammatory cells consisting of macrophages, lymphocytes, and a few neutrophiles."

The findings are those of a recurrent, acute, though not very destructive, appendicitis.

The meeting adjourned.

A. G. Schulze, M.D.
Secretary

SAFER MATERNITY—A TRIUMPH OF DEMOCRACY

We think the triumphs of democracy for human happiness stand up well when contrasted with the results achieved by the totalitarians—and they need to be publicized. Saving the lives of mothers and babies in childbirth by self-criticism and self-discipline is one good example from the field of public health of the Spirit of America.

For twenty years the maternity death rate was stagnant—despite rapid advances in the science of obstetrics. The reason was that the mothers of America were not receiving the care they needed. They died at the highest rate in the civilized world. Then it was that interested citizens began to cry out against this needless waste of life. Newspapers and magazines took up the chorus.

The medical profession in various communities began to study maternal deaths and to look into the reasons why mothers died. It was found that a large share of the blame must be placed upon the doctor's shoulders. Poor training in medical schools, obstetrical short cuts, failure to keep abreast of advances, carelessness, were some of the reasons publicly ascribed to these needless maternity deaths. The doctors, however, did not pussyfoot but willingly accepted this responsibility. Immediate efforts were made to improve the standards of care given to expectant mothers. County medical societies held special courses for those doctors doing obstetrics; efforts were made to improve the teaching of this science in the medical schools; and in a number of communities each maternal death was studied to determine how it might have been prevented. No coercion there. It was a responsibility willingly accepted for the sake of mothers and babies.

Nurses, too, sought to improve the care given during pregnancy, at birth, and afterward. The American Hospital Association studied that phase of the problem and recently announced in no uncertain terms: "A poorly managed, ill-equipped, carelessly supervised hospital is the worst place on earth for a woman to have a baby," but added, "A high grade hospital with a properly planned and well-supervised maternity department is the safest and best place for childbirth." Efforts have been made to improve maternity care given in hospitals. Many new maternity clinics have been opened with public and private funds.

All of this has cut right across lines of race and color and creed. Rich and poor have benefited alike. All of these efforts have been based upon a humanitarian purpose. They were launched not to provide more cannon fodder but for the sake of life and health and happiness of mothers and babies and for the sake of healthy family life.

What has been the result? The maternity death rate is no longer stagnant. It is falling steadily, and in many states is falling rapidly. In Connecticut, Rhode Island, and New Jersey, where this coöperation and self-criticism has reached its peak, the maternal death rate is far below the national rate.

The Nazis and the Fascists and the other totalitarians may rage at the enemies of their regimes, may carry on cold-blooded persecutions of women and children; but here in the United States we are achieving a victory against death and disaster for the sake of our mothers and babies, the very future of this nation!—Briefs, Maternity Center Association, January, 1939.

MINNEAPOLIS SURGICAL SOCIETY

Stated Meeting, Thursday, January 5, 1939

Dr. George R. Dunn, President, in the Chair

CARCINOMA OF THE PANCREAS

An Analysis of Forty-seven Treated Cases from the Lahey Clinic in Boston

D. C. MacKinnon, M.A., M.D.*

Minneapolis

Carcinoma of the pancreas is not a common form of malignant disease. It constitutes only 1 to 2 per cent of all carcinomas. In the management of this disease, difficult problems of diagnosis and treatment are encountered. From this investigation little can be added to the present knowledge of the symptomatology and diagnostic methods. However, the end-results of the surgical and radiation therapy in a small series of cases are of interest, but not very encouraging from the standpoint of accomplishing anything comparable with the results of surgical treatment of carcinoma in some of the other parts of the body.

This analysis includes forty-seven cases of carcinoma of the pancreas in which operation was performed at the Lahey Clinic, with a follow-up note in all patients until the time of death. The series does not include all cases with the operative diagnosis of carcinoma of the pancreas. A few cases with incomplete follow-up data and a number without convincing operative findings were excluded. Likewise, a few cases with obstructive lesions of a presumed malignant character in which the patient was restored to health following cholecystenterostomy were also excluded. Obviously, these lesions were not malignant in nature, and probably were cases of chronic pancreatitis or silent common duct stone associated with pancreatitis.

In thirty-five cases the diagnosis was made from a satisfactory operative description of the gross pathologic change as observed by an experienced surgeon. Of the remaining cases, seven were proved at biopsy and five at autopsy to be carcinoma of the pancreas.

The average age of these patients was fifty-six years, with the range from thirty-one to eighty years. All of the cases except four were equally distributed in the fifth, sixth, and seventh decades. There were twenty-three males and twenty-four females, a higher incidence of females than is usually found in most reports. A ratio of males to females of 3 or 4:1 is more common than the ratio found in these cases.

The average duration of the disease before admission to the clinic was 3.6 months, with the range from one to nine months. Pain frequently preceded the onset of jaundice. It was not until the pain, anorexia, and loss of weight became progressively worse, or jaundice appeared, that most of these patients came for treatment.

In the order of their frequency, the most common symptoms of carcinoma of the pancreas were weight loss, anorexia, pain, jaundice, nausea, and vomiting. Loss of weight was present in 85.1 per cent of the cases. There was no record of weight loss on the records of five patients. The average amount of weight loss was 22.7 pounds, with the range from eight to seventy-two pounds. Anorexia was reported in 82.9 per cent of the cases. Pain was present in 76.5 per cent of the patients. It occurred in the epigastrium in twenty-seven cases, in the right upper quadrant of the abdomen in eleven, and in the back in seventeen, either in one or in a combination of two or more regions. Jaundice was present in 59.5 per cent, and pruritus in 25 per cent of the patients with jaundice. Nausea occurred in 21.2 per cent, and vomiting in 17 per cent.

On physical examination, abdominal tenderness was elicited in 36.1 per cent of the patients, occurring in the epigastrium in five, and in the right upper quadrant in twelve. There was no relationship between tenderness in the right upper quadrant and the presence of distention of the gallbladder. An abdominal mass was palpable in 55.3 per cent of the cases; it was found in the right upper quadrant in eighteen, in the right upper quadrant and epigastrium in three, and in the epigastrium in five. Clinical errors in palpation were frequently observed, particularly when the cause of the masses was noted in the record of the physical examination. Nevertheless, in eighteen to twenty-one cases with right upper quadrant masses, the operative findings showed that the gallbladder was markedly distended in all of these cases.

The roentgenographic findings of extrinsic pressure on the stomach or duodenum, duodenal stasis, or widening of the duodenal loop, are valuable diagnostic data. Gastro-intestinal roentgenograms were taken in twenty-one cases; six were negative, seven showed extrinsic pressure or stasis with no widening of the duodenal loop, and eight showed widening of the duodenal loop without extrinsic pressure or stasis. Therefore, positive roentgenologic findings were noted in 71.4 per cent of the cases in which roentgenograms were taken. Such a valuable diagnostic aid should be used more frequently when carcinoma of the pancreas is suspected.

When the common bile duct is involved, additional diagnostic evidence may be obtained by examining and demonstrating the absence of bile or the presence of blood in the duodenal drainage. Duodenal drainage was done in only seven cases, but in all of these cases bile was notably absent, and in two cases blood was obtained. It must be remembered that primary carcinoma in the common duct may give similar findings.

From the operative findings, there was distention of the gallbladder in 63.9 per cent of the cases. Metastases occurred locally or to the liver in 31 per cent. The primary growth involved the head of the pancreas in thirty-eight cases, the body in two, tail in one, entire gland in four, and the pancreas, stomach and transverse mesocolon in two cases. Stones were present in the gallbladder in three cases. In the patients with associated cholelithiasis, one was jaundiced, and the gallbladder was distended, while two were not jaundiced, one with and one without gallbladder distention, showing that stones occurred in two cases in which the gallbladder was capable of distention.

---

*By invitation.

A biopsy was performed at the time of the operation in ten cases; the pathologist's report was positive in seven. All four specimens taken from the metastases to the liver showed microscopic evidence of metastatic carcinoma simplex. Four specimens were taken from the primary growth in the head of the pancreas, two were reported as adenocarcinoma, one atrophic pancreas, and one fibrous tissue with chronic inflammation. In two cases a lymph node was removed from the gastrohepatic omentum; one showed adenocarcinoma and the other simple hyperplasia. The biopsies were probably not satisfactory in the three cases with negative reports. Since the operative description of the gross pathologic change was convincing in these cases, they were included in this report. Granted that these patients are often poor operative risks, and that there are certain technical difficulties in performing a biopsy, this procedure seems justified whenever it can be accomplished without too much additional risk. When a correct diagnosis can be made, postoperative management can then be instituted more intelligently.

Considerable attention has been given to the presence of painless jaundice and distention of the gallbladder in making a diagnosis of carcinoma of the pancreas. Since pain was present in 76.5 per cent of the cases, and this figure agrees with other reports, certainly the disease cannot be painless in the majority of cases. The pain associated with this lesion is, however, much less severe than that associated with gallstone colic. Less than two-thirds of the cases showed jaundice and distention of the gallbladder. When these two factors are present, they are important diagnostic aids, indicating obstruction of the common bile duct, but they may never occur or may appear as late manifestations of the disease, especially when the primary growth in the pancreas is some distance from the common bile duct. Anorexia, progressive weight loss, and a dull pain in the epigastrium or right upper quadrant of the abdomen, boring through to the back under the angle of the right scapula, are more suggestive symptoms of this disease.

Pain is not entirely due to the distention of the gallbladder, since there is no definite relationship between these two factors in this series of cases. In thirty patients with distention of the gallbladder, nineteen gave a history of pain, and eleven had no pain, while all of the patients without gallbladder distention had pain. Pain is probably due to pressure and distention produced by the primary growth in the pancreas.

In twenty-eight cases with jaundice, there were three exceptions to Courvoisier's law, that the gallbladder is distended in malignant or noninflammatory obstructions of the common bile duct. The three cases in which the body and tail of the gland were involved, and those with associated cholelithiasis, were not in this group; therefore, no explanation can be given for these exceptions. In nineteen cases in which jaundice was not present, the gallbladder was distended in five and there was no distention in fourteen, which is even more confusing.

Weight loss was a frequent symptom definitely associated with anorexia and probably caused by a disturbance of pancreatic function. In twenty-five patients with jaundice, the average weight loss was 24.7 pounds, and in fifteen without jaundice the average loss of weight was 19.5 pounds. Although the average loss of weight was five pounds more in the jaundiced patients, the difference does not seem sufficient to conclude that jaundice caused the loss of weight. In thirty-two patients with pain and eight without pain, the loss of weight was 22.4 and 22.8 pounds, respectively, indicating absolutely no relationship between pain and weight loss.

A number of surgical procedures were used in the management of these cases. The procedures and the number of times they were performed are indicated in the tabulation.

TABULATION

Procedure	Number of Cases
Abdominal exploration (7 biopsies)	15
Cholecystogastrostomy (2 biopsies)	7
Cholecystogastrostomy and posterior gastro-enterostomy	1
Cholecystoduodenostomy	2
Cholecystojejunostomy	12
Cholecystojejunostomy and choledochostomy	2
Choledochostomy	2
Choledochostomy and cholecystostomy (1 biopsy)	2
Cholecystostomy	3
Posterior gastro-enterostomy	1
Total	47

Since nine patients died shortly after operation, the operative mortality was 19.1 per cent. Only two deaths occurred following abdominal exploration, and seven deaths were related to more extensive operative procedures. The contributory causes of death were cachexia in four cases, pneumonia in two, peritonitis following perforation at the suture line of a cholecystojejunostomy in one, hemorrhage in one, and hemorrhage and pneumonia in one case. Hemorrhage was infrequent in this series of cases, occurring only twice, and resulting in postoperative fatalities. Carcinoma of the head of the pancreas was the primary cause of death in all five cases in which an autopsy was performed.

Radiation therapy was instituted in eight cases after the patients had recovered from their operations. A cholecystenterostomy was done in five of these cases, and abdominal exploration in three. There was a marked individual variation in the amount of radiation therapy used; nevertheless it seemed worth while to consider these cases as a group and to make comparisons.

The average length of life in the thirty-eight patients who survived the operation, disregarding their methods of management, was eight and six-tenths months. Cholecystenterostomy was done in fifteen cases without radiation therapy, with an average duration of life of eight and six-tenths months. One patient in this group lived for fifty-four months after operation, but finally died of the disease. Excluding this unusual case, the average duration of life was 5.4 months in this group. Radiation was administered to five patients on whom cholecystenterostomy had been performed, with an average length of life of seventeen months. In ten cases in which an abdominal exploratory operation was performed and radiation was not given, the average length of life was 4.7 months. In three cases with radiation after abdominal exploration, the average was 16.6 months. Disregarding the surgical procedure used, the average duration of life in the eight patients who received radiation therapy was 16.8 months. Cholecystenterostomy relieved the jaundice and also the itching when pruritus was associated with jaundice. Cholecystenterostomy as compared with abdominal exploration did not produce a significant increase in the duration of life. However, when radiation therapy was used, there was a significant and proportional increase in the duration of life in both series of cases.

Of two patients who received radiation therapy, one had a cholecystojejunostomy, the other an exploratory laparotomy and biopsy with a positive report; these patients lived for forty-one and forty months, respectively. After radiation they showed marked improvement, with periods of excellent health. There was much less pain, a gain in weight and strength, and the epigastric mass was definitely reduced in size. Roentgenologic studies in one of these cases revealed a definite displacement of the duodenum, and after radiation a normal contour was found on repeated examinations. With such favorable results, this form of treatment should be used more frequently than it is at present. With added experience in radiation therapy more can be done for these patients in the future than has been done in the past.

When there is obstruction of the common bile duct below the point where the cystic duct enters, it is distinctly worth while to anastomose the gallbladder to the intestinal canal and relieve the patient of that type of carcinoma discomfort associated with jaundice.

At the Clinic, three types of palliative operation have been employed, cholecystogastrostomy, cholecystoduodenostomy, and cholecystojejunostomy. Of these procedures, only the latter one has been employed for some years. Cholecystogastrostomy is an undesirable surgical procedure, since the powerful peristaltic waves of the stomach can propel the gastric contents through the new opening into the smaller bile passages. Another disadvantage is that the wall of the stomach is thick, with a loose redundant mucosa which makes it difficult to accurately anastomose the stretched-out, thin-walled gallbladder to the stomach. When one realizes, also, that on one side of the anastomosis the stomach may move in deep peristaltic waves with digestion or vomiting, it is evident that the suture line must be exposed to considerable strain at times.

Likewise, there is a disadvantage in anastomosing the gallbladder to the duodenum. Both structures are relatively fixed so that accurate approximation and anastomosis may be difficult and at times uncertain. The duodenum is partly extraperitoneal and so does not permit of easy mobilization, so the gallbladder must be made to migrate to the duodenum. Here again the rise and fall of the liver with diaphragmatic motion which at times is of quite violent character, with vomiting, must jeopardize the security of this suture line.

Cholecystojejunostomy is the procedure which is used more frequently and has overcome the objections raised about the other two procedures. It is occasionally true that this procedure cannot be utilized when the mesentery of the jejunum is too short to permit the jejunum to comfortably reach in front of the hepatic flexure to the gallbladder. Cholecystojejunostomy is accomplished with a double row of sutures as in gastro-enterostomy. After the anastomosis is completed, a silk stitch is placed proximal and distal to the anastomosis between the jejunum and the capsule of the liver. These stitches so fix the anastomosed jejunum to the liver that it ascends and descends with any motion in that structure, taking all strain off the suture line. This is an important point when one realizes that many of these anastomoses must be made with a stretched-out gallbladder wall of almost paper thinness, and one from which stitches will tear very easily. The thinness of the jejunal wall is such that it makes the suture of these two structures easier.

In patients who have had jaundice for a long time and are poor operative risks, the employment of cholecystostomy through a small incision under local anesthesia, with later anastomosis of the gallbladder to the jejunum, has made it possible to accomplish successfully cholecystojejunostomy in patients who would not be able to stand it without this preliminary measure.

In conclusion, it is desirable to obtain a specimen at biopsy in patients suspected of having carcinoma of the head of the pancreas, to settle the matter of prognosis, and to settle the question of postoperative roentgen therapy.

Postoperative roentgen therapy definitely prolongs life in patients with carcinoma of the head of the pancreas in this series of cases.

The roentgenologic evidence of extrinsic pressure and widening of the curve of the duodenum is of value in the diagnosis of carcinoma of the head of the pancreas.

Anastomosis of the jejunum to the gallbladder instead of the stomach or duodenum is an easier and safer procedure than anastomosis of the two latter structures to the gallbladder and is functionally just as satisfactory.

I wish to thank Dr. Frank H. Lahey for the privilege of presenting this paper.

LYMPHOSARCOMA OF THE INGUINAL GLANDS

Case Report

G. R. Dunn, M.D.
Minneapolis

This patient was first seen on September 26, 1935, with a subcutaneous mass, rather irregular, firm and of a rubbery consistency, in the right groin. The white blood count was 7,100, polymorphonuclears 76 per cent, lymphocytes 20 per cent, monocytes 3 per cent, eosinophils 1 per cent. The urine was negative.

On September 26, 1935, a complete blood count was also done by Dr. Floyd Grave. The hemoglobin was 88 per cent, red blood cells 5,120,000, leukocytes 11,000, polymorphonuclears 69 per cent, lymphocytes 26 per cent, monocytes 5 per cent.

Blood taken for agglutination tests on September 28 was negative for typhoid, paratyphoid A and B, melitensis and tularense. Agglutination test was atypical in a dilution of 1 to 200 for the dysenteriæ Flexner, negative for the Shiga.

Radiographs of the lower lumbar spine and pelvis were negative for fracture, dislocation, bone injury, or disease.

Two Wassermann reactions were negative at the University of Minnesota.

The patient finally decided to permit an operative procedure and was operated on October 23, 1935. The tumor was removed en masse with a layer of underlying fascia.

Dr. McCartney of the Pathological Department of the University reported as follows: "The tumor from L. K. is oval, about 6 x 4 x 4 cm., quite firm; on section uniform in appearance; some areas of congestion but no gross hemorrhage. Near the main tumor is a rounded mass about 1.5 cm. in diameter and another which is less than 1 cm. in diameter. The smallest one is definitely a lymphnode only partially involved. Sections from the three masses show essentially the same picture except that the smallest mass, which is a lymphnode, is only partially involved. The structure is that of a tumor made of small round cells showing no definite arrangement; numerous mitotic figures are found. The normal architecture of lymphnodes is entirely replaced except in the smallest one. From a microscopic standpoint it is not possible to state whether this is lymphosarcoma or leukemic involvement of nodes. Considering the fact that only a single group of nodes are involved, one is inclined to the diagnosis of lymphosarcoma. A study of the blood would be well worth while to rule out leukemia."

This man received four series of x-ray treatments at Northwestern Hospital. The first series of deep x-ray therapy was started on October 28, 1935, the second on December 17, 1935, the third on February 4, 1936, and the fourth on March 31, 1936.

A radiograph taken of the chest on February 5, 1936, at Northwestern Hospital showed no evidence of pulmonary tuberculosis or other infiltration or consolidation. Conclusions: "Normal chest."

A blood count done on March 26, 1936, showed the hemoglobin to be 102 per cent, red blood cells 5,670,000, white blood cells 6,150, polymorphonuclears 54 per cent, lymphocytes 45 per cent, monocytes 1 per cent.

The man has been examined at intervals since the operation and x-ray therapy were completed. He was last examined on October 18, 1938, at which time a complete physical examination was done. No evidence of recurrence was found. The chest was x-rayed on October 14, 1938, by Dr. R. G. Allison, which showed no evidence of pulmonary tuberculosis or other infiltration or consolidation. Conclusions: "Normal chest."

The operation was done on October 23, 1935. At the present time, January 5, 1939, it is a little over three years with no evidence of recurrence following operative removal and deep x-ray therapy with a pathological diagnosis of lymphosarcoma.

CARCINOMA OF THE JEJUNUM

Case Report

Willard Peterson, M.D.
Minneapolis

Mr. W. B. was first seen on February 25, 1936. At this time he was having severe attacks of vomiting coming on shortly after eating or drinking. There was no pain but only a feeling of epigastric distress. His past history was essentially negative except that he had lost twenty pounds in weight in the last two months.

Examination showed a fairly well nourished male about sixty years old. The head and neck were normal. The heart and lungs were normal. Blood pressure was 145/90. The abdomen was normal for epigastric tenderness; no masses could be made out. Extremities were normal. Hemoglobin was 70 per cent.

He was admitted to Northwestern Hospital, February 28, 1936, and a gastro-intestinal x-ray study was made. Fluoroscopic and plate examination made of the stomach and cap immediately after the ingestion of a barium meal showed the stomach to be normal in size, shape and position. Peristalis was active and passed through the entire stomach. The duodenal bulb filled well and was somewhat dilated. There was a marked dilatation of the duodenum and the proximal few inches of the jejunum. There was a definite obstruction just distal to the duodenal-jejunal junction.

Examination at six hours showed a small portion of the meal in the small intestine. There was a gastric retention. The patient had probably vomited some of the barium. Fluoroscopic and plate examination of the colon showed the fluid to pass readily to the terminal ileum and showed a normal condition.

X-ray Conclusions.—Normal stomach and cap, normal colon. There is definite evidence of obstruction of the jejunum just distal to the duodenal junction. This obstructive process represents a carcinoma.

The patient was prepared for operation by gastric lavage and intravenous solutions, and on March 5, 1936, he was operated upon. A high paramedian incision was made and a small mass was made out in the proximal jejunum which was freely movable. There were no glands involved. About four inches of jejunum was resected with the mass in the center, leaving about 1.5 inches of jejunum on the duodenal side. An end-to-end anastomosis was made with three rows of invaginating sutures and a piece of omentum was sutured loosely over the anastomosis. Gastric syphonage was started at once and he was kept on liquids for about ten days. At the end of two weeks he left the hospital.

Laboratory Diagnosis.—Specimen is a section of the small bowel 7 cm. long, in the center of which is a firm constricting mass 1.5 x 2 cm. On the mucous surface over the mass is a small excavated ragged ulcer 1 cm. across. The lumen of the bowel is two-thirds occluded by the tumor.

Microscopic sections show epithelial cells with irregular gland arrangement invading the muscle and underlying the edge of the mucosa at the edge of the ulcer. Diagnosis: Adeno-carcinoma.

The patient is at present actively engaged as an engineer. He has not only regained his lost weight but has added another twenty pounds. Nearly three years have now elapsed, which is important because statistics show that practically all individuals with adeno-carcinoma of the jejunum are dead by the third year.

Dr. James Johnson has covered the subject very well in his article in the November, 1937, MINNESOTA MEDICINE, and as he is on the program I shall leave the discussion to him.

CASE REPORTS

L. H. FOWLER, M.D., and W. A. HANSON, M.D.

Minneapolis

Malignant Melanoma of Foot

A married woman sixty years of age consulted us on July 16, 1926, on account of a pigmented mole on the dorsum of the right foot. She had been treated for a gastric ulcer for several years, otherwise her past history was negative. She stated that she had had a pigmented mole on the skin of the dorsum of the right foot for twenty years. Two months before her admission this began to grow, and the center became raised and bled easily.

Examination of the right foot showed a pigmented area on the dorsum measuring 2 x 3 centimeters, with a raised hard center which was ulcerated. General physical examination was essentially negative.

Under local anesthesia, this tumor and a wide margin of normal skin was excised. The right inguinal glands were also removed.

Dr. E. T. Bell, Chief of the Department of Pathology of the University of Minnesota, examined the specimen and reported it to be a malignant melanoma. The inguinal glands showed no evidence of malignancy.

This patient was not seen again until June 6, 1934, eight years later. At this time she reported that she had recently recovered from a fractured pelvis, treated by Dr. Raiter, in Cloquet, Minnesota. Examination showed no evidence of any recurrence of the original growth of the foot. She did, however, have an ulcerating skin lesion which was eroding the nose and ear. It was not pigmented but had the clinical appearance of a basal cell epithelioma. No sections were obtained.

The patient lived in another city, where I understand she died from pneumonia complicating an erysipelas of the face.

Comment.—This case is reported to make a record of a patient with a malignant melanoma living eight years after its removal and dying from a complication of a different type of malignancy in a different part of the body.

Myxosarcoma of the Right Chest Wall

A man twenty-three years of age presented himself for examination on October 26, 1926, on account of a small lump on the lower right chest wall. His past history was negative. Two months before admission he noticed a tender nodule under the skin on his lower right chest. This increased in size rather rapidly.

General physical examination was essentially negative.

Over the right eighth intercostal space in the anterior axillary line was a hard, movable, subcutaneous tumor about the size of an English walnut.

On October 28, 1926, under local anesthesia, this tumor was removed. After pathological examination of the specimen disclosed it to be malignant, a larger area of skin, subcutaneous tissue and muscle was removed, and the base of the wound cauterized with the actual cautery. Several enlarged axillary lymph nodes were also removed.

The excised tissue was examined by Dr. J. S. McCartney, Jr., of the Department of Pathology of the University of Minnesota, who reported that the "sections of the tumor show an actively growing myxosarcoma." The axillary glands showed only inflammatory reaction.

The patient made an uneventful convalescence and is alive and well today, over twelve years since the removal of this tumor.

Sarcomatous Degeneration of an Intraligamentous Fibromyoma with Unusual Abdominal Metastasis

A married woman fifty years of age presented herself for examination on May 7, 1936, on account of a mass in the lower abdomen. She had two children, aged eight and nineteen years, living and well. Her past history was essentially negative. For the previous three months, she had felt tired, nervous and had noticed a mass in her lower abdomen. Her menstrual periods had been somewhat delayed and irregular. There had been no intermenstrual bleeding.

The general physical examination was essentially negative except for the findings in the pelvis. On bimanual examination, a large hard irregular mass was felt in the pelvis which appeared to be attached to the uterus. A diagnosis of fibromyomata of the uterus was made and operation advised.

On June 2, 1936, operation was performed at Northwestern Hospital. On opening the abdomen through a low mid-line incision, the whole pelvis appeared to be filled with a large, soft, hemorrhagic, cauliflower-like growth. On further examination this mass was found to have its chief attachment to the base of the left broad ligament. It was adherent to the bladder but was entirely separate from the uterus. The fundus of the uterus was only slightly larger than normal and contained three small fibromyomata measuring from one to three centimeters in diameter. Both ovaries and tubes were normal. There was no evidence of metastases in the liver or abdominal lymph nodes. The tumor mass was removed with some difficulty. A small piece of the bladder had to be excised with the tumor. The bladder wound was closed with two rows of chromic catgut. All bleeding was controlled and the wound closed by layers without drainage. The patient made a satisfactory recovery from the operation.

Examination of microscopic sections of the tumor was reported by Dr. Smith, pathologist of Northwestern Hospital, as follows: "Some areas are definitely myomatous, other areas show myxomatous degeneration. Many areas, especially towards the surface of the tumor, show masses of large hyperchromatic cells, embyronic in spots, with numerous mitotic figures." Microscopic diagnosis: "Myoma with sarcomatous degeneration. Origin probably from the broad ligament."

Several physical examinations during the next twenty-one months showed the patient to be in fairly good health. On March 17, 1938, she returned to us and stated that she had just noticed a slight pain and thought she could feel a "lump" in the left side of her abdomen. Abdominal examination at this time (twenty-one months after the first operation) revealed a small, hard, movable mass in the left mid-abdomen, just above the level of the iliac crest. It felt very much like a low-lying kidney. An intravenous pyelogram with twenty cubic centimeters of diodrast showed an oval shadow in the left lower abdominal quadrant which seemed to be definitely separate from the left kidney. The outline of the kidney pelves and calyces appeared to be within normal limits. Urinalysis was normal.

Examination of the colon after the instillation of a barium enema showed the outline of a kidney-shaped tumor mass in the left mid-quadrant of the abdomen which was displacing the lower end of the descending colon medially. The colon was negative for intrinsic pathology. A chest x-ray was negative for evidence of metastases. A diagnosis of metastatic sarcoma of the left mid-abdomen was made and exploration advised.

On April 7, 1938, the patient was readmitted to Northwestern Hospital and the abdomen opened through a left rectus incision. There was a large, hard, smooth round tumor about six inches in diameter found in the left mid-abdomen. It was freely movable and attached posteriorly to the parietal peritoneum at its reflection onto the descending colon. The omentum was also adherent to the anterior surface of the tumor mass. The uterus was small and contained one small fibromyoma measuring one centimeter in diameter. This was enucleated. There was no evidence of any tumor growth in the pelvis at the site of the original growth or elsewhere. Careful examination of the liver and other abdominal contents revealed no other evidence of metastases. The attachments of the tumor mass were clamped, cut and the mass easily removed. The patient made an uneventful recovery and has had no further trouble to date, which is, of course, only ten months since the second operation and thirty-two months since removal of the original growth.

Dr. J. S. McCartney examined the microscopic sections from this secondary growth and reported them to show "spindle cell sarcoma, possibly leiomyosarcoma." Sections from the primary growth in the left broad ligament show a very similar structure to those of metastatic growth.

Comment.—Many authors state that from 20 to 30 per cent of women past the age of forty years have fibromyomata of the uterus. Relatively few of these undergo sarcomatous degeneration. Much more rare are fibromyomata outside of the uterine musculature and still more rare do we find such a migrating tumor which has become malignant. It is interesting to speculate as to how this isolated, distinct, secondary tumor developed in the free abdominal cavity. Sarcomata are supposed to metastasize through the blood stream rather than via the lymphatics. But I know of no vascular or lymphatic connection between the left broad ligament and the parietal peritoneum of the left side of the abdomen. My only explanation is that a small portion of sarcomatous tissue may have been attached to the omentum at the time of the original operation. Later, this wandered to the left side of the abdomen, became adherent to the parietal peritoneum and the secondary tumor developed.

Dr. Bell and Dr. McCartney are here tonight and have very kindly consented to discuss some of the pathological aspects of these cases.

RADIATION THERAPY IN TUMORS

R. G. Allison, M.D.†

Minneapolis

X-ray treatment of malignant tumors with voltages in excess of 200 Kv. has now been done over a sufficient length of time to permit some fairly definite conclusions.

1. Unless a tumor is in some degree sensitive to radiation at 200 Kv., no response to radiation at higher voltages can be expected.
2. Tumors which are mildly sensitive to radiation with 200 Kv. can often be permanently cured with treatment at higher voltages.
3. Tumors which are extremely sensitive to radiation at 200 Kv. do not need treatment with higher voltages; in fact, recovery may be retarded owing to the increased damage which results in most cases to the surrounding normal structures from these higher voltages.

Coutard, of the Curie Institute of Paris, has for many years been working with 200 Kv. He has increased the filtration and increased the tube skin distance far above those used by other workers. His system relies on the daily administration of doses of 150 to 300 r and is carried on over a period of from three to six weeks, depending upon the size of the dose the patient can tolerate and the number of fields treated. By this method, doses of 2,000 to 5,000 r, or from three to six erythemas, can be given to each field. The reaction in the skin and surrounding structures, while marked, still permits their return to normal.

Coutard is now working with 400 Kv. and employing the same technic. He feels that in the tumors which are sensitive to radiation at 200 Kv. he has obtained better results at 400 Kv.

This method of treatment was first used by Coutard in the treatment of malignant tumors of the tonsil, larynx, and buccal cavity. This same type of method of treatment is now employed in all deep-seated malignancies as well.

Regardless of the voltage used, this method is now generally employed in the treatment of all malginant growths, occurring anywhere other than on the surface of the body.

The last few years have taught us once more a lesson that we learned years ago with radium; that is, the fact that the limitation of the dose to a given lesion is not the mechanically measured dose, but the capacity of the normal surrounding tissues to recover from the dosage. This factor determines the absolute end point to which any x-ray dose can be carried.

An interesting development that has found considerable favor in Europe is the so-called method of Chaoul, in which a small self-contained generator and x-ray tube are placed in contact with the lesion itself, either directly as in the case of accessible malignancies such as the cervix or skin, or through a surgical approach to the growth. This has been applied especially to lesions of the bowel and kidney after exposure. Such an apparatus is necessarily limited to lower voltages, the top being in the neighborhood of 90 Kv. and with the low filtration and short distances a very rapid delivery of radiation can be effected. The effect is, of course, local and cauterizing and comparable somewhat to contact application of radium except that the time of delivery of an effective dose becomes possible in a few minutes.

In the selection of patients and lesions for treatment there have been few radical changes, but there have been modifications in technic and some crystallization of ideas as to proper treatment.

---

†By invitation.

In the female where carcinoma of the breast, uterus and ovaries accounts for the largest portion of malignancy, ideas of technic have become more uniform. Carcinoma of the breast remains primarily a surgical disease with practically all workers agreeing on operation with postoperative radiation. Pfahler and Vastine of Philadelphia, in a large series of cases showing five-year statistics, advise more pre-operative radiation and their figures show definite improvement in five-year cures, where pre-operative and postoperative radiation have been used. They recommend pre-operative radiation especially in cases of Group II where axillary glands are palpable and follow a dosage of 900 r per field to each of three or four fields in two weeks by radical surgery. As soon as primary union is effected (usually in 7 to 14 days), the postoperative series is begun and a similar or larger dose is added as the patient's tolerance permits. In Group III cases they recommend a heavier pre-operative series followed by a six-weeks' wait before operation.

They quote figures from the literature of 28 per cent five-year survivals by operation alone in Group II cases which is increased to 40 per cent by postoperative radiation. In their own series of 400 cases they claim 52 per cent survivals with postoperative radiation and when pre-operative is added, 57 per cent.

A well-advised adjunct to the treatment of carcinoma of the breast in menstruating women is the production of an artificial menopause.

Experimental work in cancer strains of mice has shown a definite decrease in incidence of mammary cancer in castrated females. It seems reasonable to believe that an artificial menopause is of value and the clinical results to date have borne this out.

In the treatment of recurrence and mestasases there has been little or no important progress. It is still apparent though, from the frequent improvement and palliative response, that these patients are entitled to the benefit of a heavy course of radiation to the affected areas.

In the treatment of carcinoma of the cervix, the method advocated by Healy of Memorial Hospital in 1933 has become the predominating one. Here again the fractional method, carried out over a period of approximately four weeks using multiple ports and the intensive dosage possible by such technic, has given improved results. The dosage per field has been carried to from 1,800 to 3,000 r, depending somewhat upon the field choice.

The indications in the different groups remains more or less the same. In the few patients found in Group I with the disease definitely limited to the cervix, radium is the major factor in the treatment with x-ray added to build up the radiation dosage in the adnexa. Groups II and III are by choice first given an intensive dose of x-ray followed immediately by the use of radium. Group IV is treated largely palliatively and for this the high voltage x-ray offers the best medium of attack. With the use of heavier doses some complications such as proctitis with late stricture are being more commonly seen, as well as an atrophic type of vaginitis. With this type of treatment the attempt is made to rely on one series of combined radiation from x-ray and radium, as subsequent series do not have as salubrious a result and are subject to a higher incidence of complications.

In the gastro-intestinal tract x-ray therapy, except in some few instances, does not have much to offer. Attention should again be called to the fact that some carcinomas of the cardiac portion of the stomach are sensitive and do respond to treatment. The treatment of carcinoma of the large bowel is, on the whole, rather disappointing but occasional cases do show definite benefit. The factor of unusual response is well demonstrated by two cases of pseudomyxomatosis peritonei treated by us, in which both patients have been free from symptoms for over two years.

Discussion

Dr. E. T. Bell (by invitation): I know of no cures of carcinoma of the pancreas. One would think that a carcinoma of the tail of the pancreas might be operable occasionally but the usual story is that quite a large tumor has developed before it can be recognized clinically. We have a number of cases on our postmortem records in which there is a long clinical history but a late recognition of the nature of the disease.

Just two days ago we had an interesting postmortem which illustrates some of the difficulties of diagnosis. The patient, with the clinical picture of a carcinoma of the head of the pancreas, was in the hospital. The only discrepancy in the diagnosis of carcinoma was that by Dr. Cecil Watson's test there was some urobilinogen in the stools, more than he would expect in a malignancy. The patient was intensely jaundiced. At exploratory operation the head of the pancreas was found to be hard and the bile duct distended. The patient died and at the postmortem this hard pancreas was found to be an old fibrous pancreatitis. There was an ulcerated stricture in the common bile duct but no carcinoma present. This is very unusual but it illustrates how difficult the diagnosis may sometimes be even at exploratory operation.

We have been impressed in the last two or three years by the frequency of carcinoma in the bile ducts. Over the last two-year periods, carcinoma of the bile duct is more common than carcinoma of the pancreas.

The response to x-ray which Dr. MacKinnon spoke of is something new to me and it offers some encouragement since we have so little to offer these people.

Dr. Dunn's case is very unusual. Dr. McCartney and I have gone over this tumor again and we think it is a lymphosarcoma. It is an enormous tumor, 6 cm. in diameter, spreading out through the tissues. It showed many mitotic figures. There is no escape from the diagnosis, and yet, the patient is apparently well for an interval that is so long that we can almost call it a cure. We have two forms of lymphosarcoma, one of which is a regional tumor and the other a generalized tumor. The regional tumor corresponds with Kundrat's original definition of lymphosarcoma. The generalized form spreads through the lymph nodes all over the body and behaves like Hodgkins disease. This tumor is radiosensitive and the apparent cure is to be attributed to a combination of surgery and radiotherapy. It is a most interesting tumor and only a few cures are recorded in the literature.

I want to mention another case of a lymphosarcoma that I have seen. This patient had a tumor around the vena cava which was palpable through the abdominal wall. Upon exploration a large tumor was found wrapped around the vena cava above the renal arteries.

It was inoperable and only a biopsy was taken. It was a lymphosarcoma. The patient was given radiotherapy; he regained the 20 pounds of weight he had lost, went back to work and was well for nearly one year, after which a recurrence developed which proved fatal. That response to radiotherapy is very encouraging in lymphosarcoma, especially the regional form.

Dr. Peterson's case is also a very rare tumor, an adenocarcinoma of the duodenum. Carcinomas in the small intestine are rather infrequent. A majority of the carcinomas of the small intestine are, fortunately, of the carcinoid type. Carcinoids resemble a basal cell carcinoma of the skin. It is not a benign tumor but it usually produces obstruction early enough for operation and cure. Occasionally it gets out through the lymph nodes and spreads to the liver. Ordinarily this carcinoid produces intestinal obstruction so that an operation has to be done before it is so very far along. It is the most common form of carcinoma of the small intestine. The adenocarcinoma is less frequent and more malignant, and a three-year survival from one of those is quite exceptional.

Dr. Fowler's cases: First, the malignant melanoma. Dr. McCartney and I have reëxamined the microscopic slides and there is no doubt as to its being a malignant melanoma. The one favorable microscopic feature is that it has not penetrated deeply into the tissues. We used to think that none of these tumors were curable. You remember that about perhaps fifteen years ago Dr. Bloodgood reported a series of fifty cases without a five-year survival, and there was quite a lot of pessimism after that report for a long time. However, we have now quite a number of these, perhaps we could count up seven or eight of them in our records, that have gone by the five-year period, so we are not nearly so pessimistic as we used to be in the case of malignant melanoma. We have tried to determine what type of tumor one might hope to cure and what sort of operation would be best. The ones on our record that have survived are apparently those that had small or pedunculated tumors. If a melanoma is out on a pedicle it does not get out into the surrounding tissues so rapidly. I believe that many malignant moles are curable in the early stages.

It is difficult to give correct advice in the handling of moles. We can hardly recommend removal of all benign moles. A short time ago a man about forty years old consulted me. He had a mole on his wrist about 1.5 cm. in diameter which was obviously malignant. He had had that mole for twenty years and during the past eight years he had consulted four different physicians about its removal. Each physician told him to let it alone. In addition to the malignant mole he had about twenty benign moles over his body. Dr. Peyton removed the malignant mole and one of the large benign growths.

About half of these malignant melanomas come from moles that have been present a long time; the other half are moles of recent origin. Those are the ones that are quite disturbing, the moles that first appear in adult life. I am a little bit more uneasy about those than I am about the others. When the mole begins to grow, that is the warning signal but when it begins to grow it is already malignant.

In this connection I want to remind you that there is a benign tumor that looks just like a malignant melanoma, namely, a melanotic papilloma. I have been fooled by these half a dozen times. They will give the same kind of a story, a black mole present for years, and then a recent rapid growth and you are perfectly sure that it is a malignant melanoma. I demonstrated one once to the senior students as a malignant melanoma; upon removal it was found to be a benign papilloma full of melanin.

The first definite signs of malignancy in a mole are an increase in size and a darkening of the skin just around it. The first extension is usually just underneath the epidermis, forming a little bluish halo all around it. When this halo is present the mole is already malignant. A wide excision gives the best chance of removing the extension in the skin. If it has gone to the lymph nodes it is incurable.

A couple of years ago I sent out some follow-up letters, trying to trace patients who had had malignant moles removed. A physician in Fargo called in his patient who had had a mole removed from her cheek ten years previously. To his great surprise a small recurrence was present which proved to be maligant melanoma. I think that we may consider the twelve-year survival in this case as a cure.

The second case of a myxosarcoma is also very encouraging. It is a small tumor but definitely malignant, about Grade II, and there is a twelve-year cure. Often the surgeon is too conservative in the treatment of sarcomas. Only radical treatment offers a chance of cure.

In Dr. Fowler's second case I think that the tumor removed at the first operation is a definite sarcoma. The recurrence appears to be more malignant. In the case of a large tumor there is danger of underestimating its malignancy. Large tumors may contain areas of low malignancy as well as areas of high malignancy. The tumor behaves in accordance with its most malignant portion. This tumor will probably recur.

These fibrosarcomas, especially of the lower degrees of malignancy, have a tendency to come back at intervals. They are cyclic in their behavior. I shall illustrate with a fibrosarcoma of the thoracic wall from our records. The patient has been operated upon four times over a period of sixteen years, about four years between the recurrences. Each time the tumor has the same structure.

Dr. James A. Johnson: Tumors of the small bowel are comparatively rare—so rare in fact that standard textbooks on surgery give them very little consideration. Recently it so happened that I operated upon four cases of tumors of the jejunum, and as a result became interested enough to review the subject.

Carter states that malignant tumors of the jejunum comprise approximately 1 per cent of all those occurring in the gastro-intestinal tract. In June, 1936, there were reported only thirty-one cases of carcinoma of the jejunum in the files of the Mayo Clinic. They further stated that carcinoma of the small bowel represented only .62 per cent of all cancer of the gastro-intestinal tract from the cardiac end of the stomach to the rectum; that cancer of the colon was about eighty times as frequent as in the small intestine. In the University of Minnesota pathological laboratory files we found two cases of cancer of the jejunum in a total of 20,000 complete autopsies in adults.

The operative mortality is apparently high. In 1927 Hellström reported forty-seven cases from the Scandinavian literature with a primary operative mortality of 36.2 per cent. R. Franklin Carter, in the Annals of Surgery, 1935, collected twenty-four cases in which resection was done, with an operative mortality of 43.4 per cent.

I will now show a few slides.

Slide: This shows a percentage distribution of carcinoma in the small bowel. Seventy-two per cent occur within 18 inches of the ligament of Treitz.

Slide: This shows the x-ray of my case of carcinoma of the jejunum. You can easily see the constriction just below the ligament of Treitz. The small proximal stump of the jejunum is very dilated, as is also the stomach. The diagnosis was made preoperatively by Dr. Ude. At operation a constricting carcinoma was found with metastases to lymph nodes. It was a difficult surgical problem because the growth was about 3 inches from the ligament of Treitz and the proximal loop was so dilated and edematous that an end-to-end anastomosis could not be done. I considered doing an anastomosis of the jejunum to the third portion of the duodenum. This was recommended by Carter and appears to be a splendid procedure. I was afraid, however, that I could not safely close the edematous proximal stump of the jejunum. There is much danger of leakage in this locality. I therefore made an end-to-end anastomosis with a large Murphy button, which proved to be very successful. There was an easy postoperative course. The patient is still living two years and three months later, although there is now evidence of recurrence.

The following three slides show the specimen with involved lymphatic glands and microscopic sections.

Slide: This patient presented herself with a movable tumor mass in the left upper abdomen and a severe secondary anemia. At operation the tumor you now see was found—a large semicystic sarcoma. Sarcoma usually arises from the submucous, muscular or subserous coats. This apparently arose from the subserous coat and, as you can see, invaded the muscular layer but did not penetrate into the lumen, but assumed an external growth, which is the usual course. The microscopic section as you see it resembles a neurosarcoma. A resection was done with a side-to-side anastomosis. The postoperative course was uneventful.

Slide: This is a benign adenoma with ulceration. I feared it was malignant because of this ulceration so I resected and did a side-to-side anastomosis. She has remained well to date.

The last case is also an adenoma located high in the jejunum and produced an intussusception which resulted in a gangrenous bowel. A resection was done with a side-to-side anastomosis. The patient has remained entirely well.

We have probably paid too little attention to tumors of the small bowel in the past. It is quite possible that we will be able to diagnose them more often now since x-ray technic of small bowel lesions has recently become more efficient.

I want to congratulate Dr. Peterson on having such an interesting case, and on the result that he obtained with an end-to-end anastomosis in this locality. It certainly demonstrates to me that his technic was carefully executed.

Dr. William Peyton: I came in late and missed the first part of the program so I will have to confine my remarks more or less to the last part.

In the treatment of malignant tumors I have been impressed by the fact that one cannot always depend upon a tumor to act in any predicted manner because it belongs to a certain type and is graded as to degree of malignancy by the pathologist. Regardless of how far one carries out classification there is at times extreme variation in the reaction of individual tumors following surgery or irradiation. This gives one a certain amount of optimism in the treatment of malignancy, since occasionally when a tumor from its general class would be expected to be extremely radioresistant, yet it is to one's surprise found to promptly disappear under treatment, or a tumor seems to be almost impossible of complete removal by surgery, yet freedom from recurrence is of long duration or even permanent. On the contrary, however, one may have every reason, from the nature and extent of the lesion, to expect a favorable result from surgery, only to have prompt recurrence.

Concerning melanoma, I might say that this patient

AN EFFECTIVE TREATMENT FOR

TRICHOMONAS VAGINITIS

An effective treatment by Dry Powder Insufflation to be supplemented by a home treatment (Suppositories) to provide continuous action between office visits. Two Insufflations, a week apart, with 12 suppositories satisfactorily clear up the large majority of cases.

with malignant melanoma mentioned by Dr. Bell is still well (tumor removed April, 1937). It was removed under general anesthesia and this point, the use of general anesthesia in tumors that are possibly malignant, I wish to emphasize. It has been my impression for some time that local infiltration anesthesia does occasionally spread malignant tumors. There is evidence from animal experiments to be found in the literature that trauma does cause tumor metastases. Some data that I have collected in experiments on tumor-bearing mice does, I think, definitely confirm the clinical impression that infiltration anesthesia may produce metastases. It does not produce metastases in every case but in a large number of mice with tumors more metastases are found in the lung of the experimented group where the tumor has been removed under local infiltration anesthesia than in the control mice in which all other factors have been the same, but local infiltration anesthesia omitted. No objection is made to regional or distant block anesthesia but only to infiltration of the tissues about the tumor.

The question of when to remove moles is a question which, as Dr. Bell says, is very difficult. I do not know, and I do not think any one knows, when to remove them. My practice is to remove melanomata that are so located that they are apt to be irritated or if otherwise located and they show signs of growth. A mole may become irritated and inflamed and look very much as though it were malignant but you get it out and it is found to be inflammatory and not malignant. I have seen a hemangioma occur in a mole and give it all the appearances of malignant melanoma until we got it out and under the microscope.

In regard to irradiation therapy I want to make a few remarks concerning our own experience and some impressions I have from the literature.

I think that in carcinoma of the breast, irradiation is of distinct value. My impression from the literature is that it improves the five year result by about 10 per cent. Our results in intra-oral carcinomata have been very much improved since we started to use the Coutard, divided dosage, type of therapy. I do not think we have had any favorable results in carcinoma of the stomach or colon following x-ray therapy if one excludes the rectum. Even in the rectum definitely good results have not been numerous. I thought we had a five year cure by irradiation in a case of carcinoma of the rectum presented at a pathological conference, but Dr. Bell, on examination of the tissue from which the diagnosis was made, told us that we did not have carcinoma in the first place. It must have been a diverticulitis. Some of the reported cures of carcinoma of the rectum are no doubt to be accounted for by similar errors in diagnosis.

Dr. J. S. McCartney (by invitation): Dr. Bell, I think, has pretty well discussed the various features of these tumors, but my name had been mentioned so often I ought to defend myself. We run what we sometimes call the Ph.D. and Master's examination among ourselves, when we get a tissue offering particularly difficult diagnosis, the juniors speaking first. Of all the things that come in, it seems to me that lymph nodes and moles give us the greatest trouble in arriving at a satisfactory diagnosis, moles particularly, because they can produce practically any picture that one might ask for, simulating spindle cell sarcoma, round cell sarcoma, individual groups of cells which one might confuse with the cells of a hypernephroma or a nephroma whichever you prefer to call it, alveolar sarcoma, etc. Sometimes we are in a lot of doubt as to just whether a given mole is malignant and whether it is a mole at all.

This particular mole that we have here is certainly quite a superficial one and this feature, as Dr. Bell said, is one of the encouraging features and one reason to think that a cure might be obtained.

I might mention the tumor reported by Dr. Dunn. This really was composed of three nodules, the largest 6 cm. in the maximum diameter, the second about 2 cm. in diameter, and the third, which was definitely a lymph node, 1 cm. in diameter. This lymph node is only partially replaced by this process. The normal structure of the node is completely replaced in the other two masses, the tumor cells are spreading out into the adjacent adipose tissue and, as I said at that time, there is a question of whether it is a lymphosarcoma or perhaps a leukemia, and I suggested an examination of the blood for leukemia. That blood examination was negative. It is very difficult at times to make a differentiation on a single section of a node as to whether it is lymphosarcoma or a leukemic type of change.

This myxosarcoma is a tumor that I would be very decidedly afraid of. It is a tumor that might metastasize and, although we do not ordinarily expect regional node involvement with sarcomas, occasionally that does happen. We have seen one or two instances where osteogenic sarcomas of bone have metastasized to regional nodes. The same thing applies to other sarcomas. Of course, one feature we don't like in this particular tumor is the myxomatous feature. A myxoma is always a worse tumor than is an ordinary connective tissue tumor of about the same degree of differentiation.

There might be some question in Dr. Fowler's case as to the justification of the name "spindle cell sarcoma." I made that last Spring and in looking at the section again yesterday it is a question whether that diagnosis is really justified, and whether it should not be called a fibrosarcoma of perhaps grade II or thereabouts.

Dr. L. H. Fowler: I wish to thank the gentlemen for their very kind discussions. I might ask Dr. Allison if the spindle cell or fibrosarcoma are susceptible to x-ray therapy at all.

Dr. R. G. Allison: In answer to Dr. Fowler's question, I think they are less susceptible than other types of malignancy. In fact, we have been unable to make any impression on them at all with 200 Kv. I think they are less susceptible than any other type.

BOOK REVIEWS

CORONARY THROMBOSIS AMONG PERSONS LESS THAN FORTY YEARS OF AGE*

A Study of Thirty Cases

WILLIAM H. GOODSON, JR., M.D., and FREDRICK A. WILLIUS, M.D.

Rochester, Minnesota

ONE of the alarming problems of present-day medicine is the increasing incidence of coronary thrombosis and its more frequent occurrence in the younger age periods of life. The first description of the disease with correct clinical diagnosis in this country is found in Herrick's classical article of 1912. In the article he cited two cases in which the patients were young persons, one a man thirty-two years of age, the case reported by Chiari, and the other a man thirty-seven years of age, the case reported by Merkel.

Our interest in the occurrence of coronary thrombosis of young patients involves the broader concepts of coronary sclerosis and atherosclerosis and this study was undertaken to investigate various clues with special reference to the genesis of the disease.

Material

Thirty cases of unquestioned coronary thrombosis comprised the basis for this study. The criteria on which the cases were selected included (1) typical histories of the disease given by patients who had experienced attacks before they came under our observation and who had electrocardiographic relics, and (2) typical clinical phenomena discovered in examination of patients who suffered thrombotic closure while under observation at The Mayo Clinic, confirmed by characteristic electrocardiographic changes or verification at necropsy.

Incidence by Age and Sex

All but three patients were recorded as being between the ages of thirty and thirty-nine years. One of these patients was twenty-two years of age and the other two were twenty-nine. The average age for the group, exclusive of the three patients who were less than thirty years of age, was 34.7, while that for the males was 34.7 years and for the females 34.6 years.

However, the occurrence of coronary thrombosis somewhat later in the lives of women than of men has been emphasized by Willius in a series of 370 cases.

There were twenty-four males and six females, a ratio of 4:1. This is in line with all previously reported studies of the sex incidence of coronary thrombosis. The sex discrepancy of coronary disease is one of the most intriguing problems of the many that remain unsolved and, as intimated in a previous study,[1] may ultimately be answered by studies in biochemistry.

Racial Trends

The number of cases in this group was not sufficiently large to permit the derivation of reliable racial trends. Sixteen patients were of American parentage while the remaining patients were fairly equally divided among seven foreign ancestries.

Hereditary Trends

The occurrence of coronary disease among patients whose family histories reveal the repetition of cardiovascular disease among their ancestors has repeatedly been the basis for comment. In a recent study of 300 cases of coronary thrombosis, Goldsmith and Willius showed that a family history of cardiovascular renal disease occurred in 55 per cent of the cases. In this study, 65 per cent of the patients related family histories which included angina pectoris, coronary thrombosis, sudden death, or "heart disease." The hereditary trend in this study closely paralleled that referred to in the previous report.

---

*From The Mayo Foundation (Goodson) and the Section on Cardiology (Willius), The Mayo Clinic, Rochester, Minnesota.

The previous illnesses experienced by these patients were in no sense unusual but represented the usual infectious diseases of childhood and adolescence and could in no manner be related to the premature development of coronary disease. In three cases the history of previous rheumatic fever was elicited but in no instances were relics of cardiac disease demonstrated and it appeared improbable that the coronary changes were associated with antecedent rheumatic coronary arteritis.

Use of Tobacco

Concerning twenty-six of the patients, the history of the use of tobacco was recorded. Nineteen (73 per cent) smoked cigarettes; nine smoked excessively and ten moderately; seven did not smoke. None of the women were recorded as smokers. As these figures are not controlled they are only of passing interest, but this subject is under investigation at present on a much broader scale.

Other Clinical Data

In eight cases the anginal syndrome preceded acute coronary closure by an interval of from one day to six months. The average interval was a month and a half. In the remaining twenty-two cases, coronary thrombosis was the first expression of the disease.

Three patients were engaged in strenuous work when the arterial closure occurred, eight were participating in moderate activity, four had just completed a meal, three had just awakened from sleep, while the status of activity of the remaining twelve patients was not determined.

In three cases the attack was without pain; one patient experienced severe nausea, another a feeling of suffocation, and the last a sense of distention. In the other cases the conventional phenomena of the disease were present.

Electrocardiographic Findings

Electrocardiographic examination was conducted in twenty-nine cases. The patient who was not subjected to this examination was under observation at The Mayo Clinic only a short time before death occurred, but postmortem study revealed acute infarcts. Owing to certain unusual features, the case of this twenty-two-year-old woman will be detailed later.

The electrocardiograms of twenty-four patients clearly verified the clinical diagnosis of coronary thrombosis. In five cases, electrocardiograms that were made a considerable time after the occlusion were essentially normal.

The infarcts, as indicated by the electrocardiographic patterns,[2] were in the anterior wall of the left ventricle in nine cases. Eight of the electrocardiograms were of the T_1 pattern while one was of the Q_1T_1 pattern. In fifteen cases the infarcts were in the posterior basal portion of the left ventricle, the region customarily supplied by branches of the right coronary artery. The patterns were of the T_3 type in nine cases, of the Q_3 type in two cases, and of the Q_3T_3 type in four cases.

The incidence of infarcts of the posterior basal region of the left ventricle in this group greatly exceeds that previously reported and may be a wholly coincidental occurrence.

Mortality

At the time of conclusion of this study eight patients (26.6 per cent) were known to be dead and their average period of survival following the first thrombotic occlusion was twenty-two months. Two died the day of the second occlusion. Ten (28 per cent) of the patients ultimately had two attacks of coronary thrombosis ranging from one month to six years following the first. In one case in this series, previously reported by Smith and Bartels, there were at least four infarcts; the conglomerate involvement of the myocardium made accurate delineation impossible, although the anterior right coronary artery was completely occluded at two points, the anterior descending branch of the left coronary artery at one point and an anomalous left circumflex artery at two points.

Postmortem examination was conducted in five cases, which included four males and one female.

The first case, that of a man thirty-five years of age at death, already has been mentioned.

The heart weighed 715 gm. and was the site of multiple infarcts. In the coronary arteries, evidence was found of atherosclerosis, grade 3. The second case was that of a man, thirty-six years of age at death. A huge, acute infarct involved the apex of the left ventricle. The anterior descending branch of the left coronary artery was completely obstructed by a fresh thrombus. The heart weighed 540 gm. Atherosclerosis, grade 3, of the coronary arteries, was present.

In the third case the patient was a man who died, aged thirty-seven years. An extensive, healed infarct of the left ventricle near the apex was found. Considerable myofibrosis of the left ventricle was present. The heart weighed 450 gm. Atherosclerosis, grade 2+, of the coronary arteries was present.

The patient in the fourth case, a man, died at the age of thirty-eight years. Postmortem examination revealed an acute infarct of the left ventricle corresponding to the distribution of the anterior descending branch of the left coronary artery. Also, there was a healed infarct involving the posterior basal region of the left ventricle and resulting from a previous thrombotic occlusion of the right circumflex artery. The heart weighed 457 gm. Examination of the coronary arteries disclosed atherosclerosis, grade 2.

The fifth case merits special consideration owing to certain unusual circumstances and owing to its similarity to a case reported by White, Glendy and Gustafson. The patient, a woman, twenty-two years of age, was in the third month of her first pregnancy when death occurred. The onset of her fatal illness coincided with a fall from a low porch, at which time a head injury was sustained. She was found on the ground unconscious and did not regain consciousness before her death, sixteen hours later. In view of the postmortem findings it could not be ascertained whether the fall was occasioned by the severe pain of coronary thrombosis or whether coronary thrombosis occurred as a consequence of a head injury resulting in shock and unconsciousness. There was an acute infarct of the posterior wall of the right ventricle and likewise a linear infarct in the central portion of the interventricular septum, extending from the base to the apex. The heart weighed 282 gm. and there was no atherosclerosis of the coronary arteries. Examination of the brain disclosed petechial hemorrhages in the cortex of the right frontoparietal region.

Comment

The report of these cases of coronary thrombosis of young persons is justified in again emphasizing the fact that this disease is occurring with increasing frequency among young persons. Likewise, it is intended to recall to mind the fact that an alert suspicion regarding its occurrence among young people must be maintained. The general phenomena of coronary thrombosis of the young do not differ materially from those of the same condition when it affects older persons.

LATE RESULTS OF THORACOPLASTY*

HERBERT A. CARLSON, M.D., HERBERT A. BURNS, M.D., and
OWEN H. WANGENSTEEN, M.D.

Minneapolis, Minnesota

ANY attempt to evaluate thoracoplasty as a therapeutic measure for pulmonary tuberculosis must be based upon recognition of the fact that thoracoplasty patients constitute a limited and select group. Only a comprehensive survey of the fate of a large, unselected series of tuberculous patients treated by diverse medical and surgical means serves to place the operation of thoracoplasty in its true perspective. Data now being collected at the Minnesota State Sanatorium will soon permit an analysis of the results of treatment of all patients admitted to the Sanatorium. In that study, however, reference to the thoracoplasty series will necessarily be so brief that we wish, at this time, to report in more detail follow-up data pertaining to fifty patients subjected to thoracoplasty prior to January 1, 1937.

All of the patients in this series originally admitted to the Minnesota State Sanatorium were operated on at the University of Minnesota Hospital over a period of eleven years (1926 to 1936, inclusive). Patients operated on for tuberculous empyema were excluded. The fifty thoracoplasties were performed in multiple stages totaling one hundred and thirty-one primary thoracoplasty operations. Subsequently five of the patients required revision of thoracoplasty performed in eight stages. The fifty patients, therefore, were subjected to a total of one hundred and thirty-nine thoracic operations. As some State Sanatorium patients have been operated upon elsewhere and as the University Hospital admits patients from other Sanatoria, the series obviously represents only a fraction of the thoracoplasty experience of the two institutions, but it seemed best to restrict the study to those who had had the same institutional care in order to present a more uniform series and to avoid duplicating follow-up studies that may be reported elsewhere.

Analysis of Material

All of the patients but two were of the white race, one being Chinese, the other part white and part Chippewa Indian. The ages at the time of operation varied from seventeen to fifty years. As nineteen (38 per cent) were past thirty-five years and nine (18 per cent) past forty years, patients regarded as "old for thoracoplasty" were well represented. Women outnumbered the men 31 (62 per cent) to 19 (38 per cent).

It is hardly possible to present an adequate picture of the extent and character of the pulmonary disease of this group of patients by means of any system of classification. All were classified as far-advanced. Productive lesions were the rule, but in about 10 per cent of the cases the disease was predominantly exudative. All had cavitation. In twenty-six (52 per cent) the disease was essentially unilateral, in twenty-two (44 per cent) bilateral with unilateral cavitation, and in one (2 per cent) bilateral with definite bilateral cavitation.* Measurement of cavities on the x-ray film revealed that in twelve (24 per cent) the cavity measured 2 cm. or less in diameter, twenty-four (48 per cent) measured 2 to 5 cm., and thirteen (26 per cent) more than 5 cm.* Lesions of the left side predominated, the more extensive lesion occurring on the left in thirty-one (62 per cent).

Definite shift of the mediastinum to the affected side occurred in thirty (60 per cent). Dense shadows with mediastinal retraction indicating atelectasis or extensive lung fibrosis occurred in twenty-three (46 per cent). Bronchiectasis was demonstrated by bronchography in only six (12 per cent) but as the earlier patients did not have lipiodol aspirations the actual incidence of dilated bronchi was undoubtedly greater. Other associated thoracic conditions were as follows: pneumothorax three (6 per cent), pleural effusion two (4 per cent), oleothorax one (2 per cent), calcification of pleura one (2 per cent).

Technic of Thoracoplasty

Since 1926 when the first thoracoplasty in this series was performed, the technic of operation has undergone a gradual evolution. From 1926

---

*From the Minnesota State Sanatorium and the Department of Surgery, University of Minnesota.

*One patient not classified.

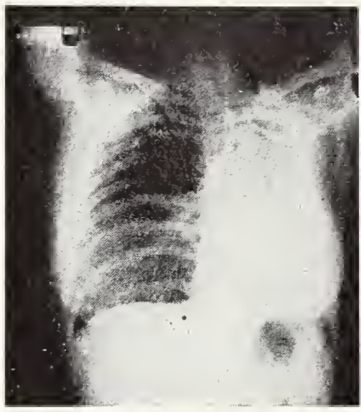
through 1930 the operation usually consisted of a paravertebral resection of eleven ribs, performed in two stages (Fig. 1). Only two of the fourteen patients operated on during that period had resection of less than ten ribs. The lower stage operation was performed first in three cases. All others had the upper stage performed first. This stage consisted of resection of five or six or even seven ribs. The segment of rib removed was seldom longer than 12 cm. and the resection of the first rib in some instances was limited to the removal of as little as 1 cm. of rib.

From 1931 through 1933 the operation was modified in that longer rib segments were removed. Six of the sixteen patients operated on during this period had antero-lateral thoracoplasty performed as the final stage. Only five patients among the sixteen had resections of less than ten ribs.

Beginning in 1934 a further modification of the technic of thoracoplasty was introduced at the University Hospital by O. H. Wangensteen. This modification consisted of performing an anterior chondrocostectomy as a preliminary stage. A week or two later total resection of the upper three ribs was performed through a posterior incision. A second posterior operation consisted of resection of two or three or four more ribs. The resulting thoracoplasty involving five to seven ribs and including complete removal of the upper three or more ribs and costal cartilages was often found to be adequate but if necessary an additional stage was performed to include resection as low as the ninth or tenth rib (Fig. 2).

During the period 1934 through 1936, fifteen of twenty patients had resection of less than ten ribs and ten patients had resection of less than eight ribs. Attention was also directed toward further shortening the posterior segment, the rib being divided under the transverse process or the transverse process itself being resected with the rib close to the body of the vertebra. It was during this period also that the extrafascial apicolysis of Semb was popularized but only three of the patients referred to here were subjected to extrafascial apicolysis. A more complete description of the technic developed during the years 1934 to 1936 is reported elsewhere by Wangensteen, Carlson and Bowers.

The anesthetic employed in most instances was nitrous oxide or ethylene, although cyclo-propane is now preferred. Novocaine infiltration was used occasionally but was regarded as less satisfactory than modern inhalation anesthesia.



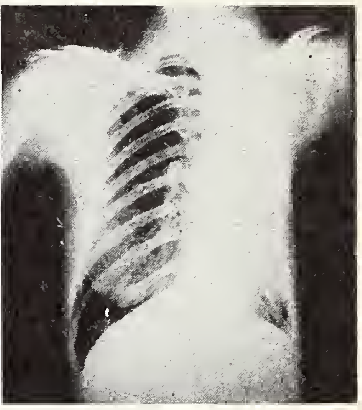


Fig. 1 *(left)*. Example of paravertebral thoracoplasty performed in two stages in 1928. Eleven ribs were resected but collapse is unsatisfactory because only short paravertebral rib segments were resected. The patient is still alive ten years after operation but sputum is positive, cavity open.

Fig. 2 *(right)*. Example of thoracoplasty performed in four stages in 1935. The upper four ribs and costal cartilages were completely removed and six additional ribs were resected. Anatomical collapse is much superior to that shown in Figure 1. The patient is alive, practically without symptoms, sputum is negative, cavity closed.

Late Results

In our study of the late results of thoracoplasty, information was obtained from sanatorium records, x-ray examination, bacteriological study of the sputum, and also by questionnaires sent to patients and physicians. Chief reliance is placed upon recent x-ray and sputum examinations. In this connection it must be obvious that the manner in which data are collected is fully as important as the tabulated statistics. Such terms as "positive" or "negative" sputum are meaningless unless one first establishes a definition of negative sputum based upon definite, rigid criteria. The question of whether a cavity is "open" or "closed" on x-ray examination is also subject to wide interpretation. Negative sputum, as defined here, denotes that guinea pig inoculation of sputum has been reported negative following a succession of negative monthly flotation tests over a period of not less than six months and that subsequently during the patient's residence in the sanatorium or after discharge to his home over a period of months or years the sputum has consistently remained negative.

X-ray interpretation in recent years has been more accurate than formerly due largely to the more frequent employment of special technic,

TABLE I. RESULTS OF THORACOPLASTY
(Status of sputum and cavity in 1938)

		Year of Operation			Totals
		1926-1930	1931-1933	1934-1936	1926-1936
Living	Cavity closed and sputum negative	5 (36%)	9 (56%)	11 (55%)	25 (50%)
	Status of sputum or cavity doubtful	2 (14%)	2 (12%)	4 (20%)	8 (16%)
	Cavity open or sputum positive	2 (14%)	1 (6%)	2 (10%)	5 (10%)
Dead		5 (36%)	4 (25%)	3 (15%)	12 (24%)
Total number in each period		14	16	20	50

TABLE II. INFLUENCE OF SIZE OF CAVITY ON RESULT
(Status of sputum and cavity)

		Size of Cavities			
		0-2 cm.	2-5 cm.	More than 5 cm.	Totals
Living	Cavity closed and sputum negative	10 (83%)	10 (41%)	5 (38%)	25 (50%)
	Status of sputum or cavity doubtful	0	7 (30%)	1 (8%)	8 (16%)
	Cavity open or sputum positive	0	3 (12%)	2 (15%)	5 (10%)
Dead*		2 (17%)	4 (17%)	5 (38%)	12 (24%)*
Totals		12	24	13	50

*One patient not classified—Films not found.

such as increased penetration, Bucky diaphragm, stereoscopic, lateral or oblique films, or the introduction of lipiodol. Despite these advances the roentgen film does not give infallible evidence concerning the fate of pulmonary lesions that have been collapsed by thoracoplasty. In presenting our data, therefore, it seemed best to combine the evidence obtained from both x-ray and sputum examinations (Table I). Comparison of the data in three successive periods (Table I) suggests that improved results have been obtained in recent years although the most recent period (1934-1936) contains the greatest number of patients in which the results of treatment are not clearly determined. One recent patient, for example, is classified among the doubtful results merely because of a recent positive guinea pig report despite the fact that the sputum has repeatedly been negative on flotation tests.

X-ray films permit us to compare the degree of collapse obtained by the modern thoracoplasty as compared with that performed earlier. Films of patients operated on during the years 1926 to 1930 reveal that only a partial collapse of the thoracic cage was attained, a collapse which we now consider inadequate (Fig. 1). During the years 1931 to 1933 the collapse was more satisfactory but in many instances still inadequate. Since 1934 the collapse of the upper portion of the thoracic cage has almost invariably been good (Fig. 2). Comparison of films of these three different periods reveal quite clearly that failure to obtain the desired clinical result in some of the earlier cases was, without doubt, due to the incomplete removal of segments of ribs in the region of pulmonary cavities.

The x-ray films also provide an interesting record of changes occurring on the unoperated side. In three instances (6 per cent) the contralateral lung was worse after operation, in thirty-eight (76 per cent) it remained practically unchanged and in eight (16 per cent) it showed definite improvement.*

---

*One not classified.

The results of thoracoplasty are not determined entirely by the type of operation but are influenced primarily by certain characteristics of the pulmonary disease such as the size of cavities, thickness of cavity walls, bronchial stenosis, bronchiectasis, thickened pleura, et cetera. Evidence presented in Table II supports the belief that the size of the cavity is important, as cavities measuring 2 cm. or less were closed about twice as frequently as those measuring more than 5 cm.

Health of Surviving Patients

Answers to questionnaires from patients and physicians reveal that of the thirty-eight survivors all but one report clinical improvement and three are entirely symptom-free. Seventeen are known to be working full time or part time, eleven are living at home but are unemployed, three failed to report whether they were working, and seven are still in the sanatorium.

Six of the seven patients who still reside in the sanatorium are ambulant or semi-ambulant; one, as a consequence of a mixed tuberculous empyema, must remain in bed. One patient of this group has a negative sputum and is about ready for discharge, the sputum of another is positive only on guinea pig inoculation but in this case the presence of a slit-like cavity has been demonstrated by x-ray. The other five patients have positive sputum on flotation. One of the latter has a tuberculous laryngitis.

Further surgery has been recommended for three of the patients now residing in the sanatorium. Additional surgery is definitely contraindicated in the case of the patient with empyema referred to above because of extensive pulmonary disease.

Mortality

It will be noted (Table I) that twelve (24 per cent) of the patients are now dead, eighteen months to twelve years after operation. This tabulation includes deaths from all causes and, obviously, should not be considered as a report of operative mortality. Only one post-operative death occurred among the fifty primary thoracoplasties performed in 131 stages. The case operative mortality, therefore, is 2 per cent; the stage operative mortality is 0.7 per cent. All other deaths occurred from six months to thirty-nine months after operation.

One of the late deaths was also due to operation as it occurred following a revision operation performed one year after the patient had survived the original three-stage thoracoplasty, including an extrafascial apicolysis. This patient was one of five who had revision of thoracoplasty performed in eight stages. The case mortality for revision of thoracoplasty in this small series, therefore, was 20 per cent.

Ten deaths remain to be explained. Six are *known* and two others are *believed* to have been due to progress of the tuberculosis. One patient who had a negative sputum and a closed cavity on x-ray examination died of glomerulonephritis (no necropsy); one who at necropsy was found to have quiescent pulmonary disease (cavity closed by thoracoplasty) died of cardiac disease three years after thoracoplasty.

Comment

The late results reported here appear to be somewhat better than the collected statistics of Hedblom and Van Hazel, which include the experience of Bull, Key, Schedtler, Denk and others. They found that "among 3,762 patients followed for from one to twelve years after operation 35.3 per cent were free from symptoms and bacilli and were able to work; 22.1 per cent were improved and able to do some work; 5.5 per cent were not improved or were made worse by the operation; 3.5 per cent were not traced; 33.6 per cent were dead at the time of the report." On the other hand our data are not so encouraging as the more recent statistics of Haight and Alexander, who have reported on the results of the *modern* type of thoracoplasty performed upon 119 patients with cavernous pulmonary tuberculosis and positive sputum, with or without empyema, from the latter part of 1932 to the end of 1934. "Ninety-nine or 83.1 per cent of these patients have completely closed cavities and persistently negative sputum." However, direct comparison of these statistics is hardly possible. It suffices for our purposes to present the data pertaining to our particular group of patients and to stress the fact that tabulated results depend fully as much on the selection of patients for operation, the time that has elapsed since operation and the criteria for "negative sputum" and "closure of cavity" as on surgical methods.

The number of patients that have returned to work is not regarded by us as an accurate test of the success of thoracoplasty. Whether a patient works or not depends upon a number of conditions or attributes not necessarily related to physical health, such as ambition, confidence, capacity to become rehabilitated, and opportunities for employment. Some patients are known to have sought and found employment when their physical condition or sputum status contraindicated it; others, who appeared to be capable of working, remain idle.

Summary and Conclusions

1. A survey of the fate of fifty thoracoplasty patients eighteen months to twelve years after operation reveals that 76 per cent are living, 24 per cent are dead.
2. The primary case operative mortality was 2 per cent; the stage operative mortality 0.7 per cent.
3. One-half of the patients (50 per cent of the entire group) have both closed cavities on x-ray examination and negative sputum, including guinea pig inoculation.
4. Comparison of x-rays of three different periods (1926-1930), (1931-1933), (1934-1936) demonstrates that improved collapse has been obtained by modification of the technic of thoracoplasty.
5. The results of thoracoplasty are determined primarily by the pathologic characteristics of the pulmonary disease of patients selected for operation.

PRIMARY CARCINOMA OF THE PANCREAS*

JUSTUS OHAGE, M.D.

Saint Paul, Minnesota

PRIMARY carcinoma of the pancreas presents a painstaking but not insuperable diagnostic problem. We have reviewed thirty-nine cases recorded at the Ancker Hospital, Saint Paul, since 1925 and find that correct preoperative diagnoses were entered in at least fifteen cases (38 per cent). Though no biopsies of pancreatic tumors were made at the time of operation, all cases were proved by autopsy (thirty-four) or by operation (five).

The diagnosis is largely by exclusion. Most commonly, cancer of the head of the pancreas must be differentiated from stone in the common duct. For this purpose, the Watson test is very helpful. It should also be noted that, contrary to the usual teaching, jaundice is not a cardinal symptom of cancer of the head of the pancreas. It was not present in at least four and probably seven of the thirty-nine cases reviewed. X-ray examination of the stomach and duodenum, with negative findings except for the possible presence of an extrinsic mass, is also a very valuable procedure in establishing a diagnosis of primary carcinoma of the pancreas.

Incidence

Cancer of the pancreas is not a rare disease. Primary carcinoma of the pancreas represented 4.8 per cent of all carcinoma cases in Massachusetts hospitals from 1928 to 1930, a survey by Howard M. Clute showed. Lewis reported an incidence of from 1.5 to 2 per cent; Hoffmann reported 3 per cent; N. Logan Leven reported from 1 to 2 per cent; F. W. Herrmann reported from 1.5 to 2 per cent. Our thirty-nine cases represent an incidence of 1.4 per cent of all the cases of carcinoma recorded at the Ancker Hospital since 1925.

Cancer of the pancreas was more common among males than among females, in the ratio of 2.5 to 1. There were 27 males and 12 females in the series. The disease is most common in the fifth and sixth decades. The average age of the patients in this series at the time of admission to the hospital was sixty-one years; the oldest, eighty-three, the youngest, twenty-seven. However, one case has been reported in a child two and a half years of age, and another in a newborn infant.

---

*Thesis presented before the Minnesota Academy of Medicine, October 12, 1938.

Tumors of the pancreas seem to be overwhelmingly carcinomatous. In reviewing 132 cases of tumors of the pancreas, Lewis found 127 to be carcinoma, two sarcoma, two cysts, and one a syphiloma.

Etiology

Exact knowledge as to the etiology of carcinoma of the pancreas is no further advanced than knowledge of cancer elsewhere in the body. Among the factors suggested as leading to the development of carcinoma of the pancreas are: (1) chronic pancreatitis, (2) gallstones, (3) cholecystitis, (4) alcoholism, (5) trauma, (6) developmental defects, and (7) syphilis.

Since only one case of syphilis (positive Wassermann) was recorded among the thirty-nine cases which we reviewed, it seems rather doubtful that syphilis need be considered an important etiologic factor in the development of carcinoma of the pancreas.

The carcinoma may be: (1) scirrhous, (2) medullary, or (3) gelatinous. It may originate from: (1) the epithelial cells of the ducts; (2) the parenchyma of the gland; or (3) very rarely, from the islands of Langerhans. Walters says that 20 per cent of the tumors of the pancreas are inflammatory.

In the thirty-four cases of primary carcinoma which came to autopsy, only the head of the pancreas was involved in twenty-three, which is almost 60 per cent. The body of the pancreas was involved in five, the tail in three, the entire gland in three.

Diagnosis and Symptomatology.—The textbooks teach that epigastric pains and jaundice are among the cardinal symptoms of carcinoma of the pancreas. Osler states that the points of greatest importance in the diagnosis are intense and permanent jaundice with dilatation of the gallbladder, rapid emaciation and a tumor in the epigastric region. Rose and Carless state: "The condition is not necessarily painful in the early stages . . . as it develops it becomes more painful and the patient wastes away and loses appetite and energy. Jaundice gradually supervenes and becomes absolute, with an enlarged gallbladder."

Our observations run somewhat counter to these teachings. It is true that thrity-seven of our thirty-nine cases had epigastric pain, radiating to the back and varying from mild to severe colicky pains. In most cases, however, the pain was mild and did not require sedatives. There was a sensation of fullness and epigastric distress, especially after nourishment.

As for jaundice, it was by no means a constant finding. It was positively reported in only twenty-four of our thirty-nine cases. In four of the patients who did not show jaundice, autopsy revealed that there was no involvement of the common duct either by extension of malignant growth or by compression. In one case, an anatomical anomaly, the common duct passed completely over the head of the pancreas without penetrating it. Lake and Marshall state that developmental abnormalities of the pancreas are not uncommon. Obviously, if the development of carcinoma in the head of the pancreas fails to involve the common duct, jaundice will not occur.

The most common findings in carcinoma of the pancreas were weakness and loss of weight, suffered by all thirty-nine patients in our series. The average weight loss was twenty-eight pounds.

The average duration of symptoms was three months; longest, eight years, shortest, two weeks. Nausea and vomiting occurred in twenty-eight of the thirty-nine cases. In nineteen cases there was a palpable mass; in twenty-two, liver enlargement; in ten, gallstones. Urinalysis was negative in thirty cases, but seven patients had nephritis. There were only two cases of diabetes, lasting from three to five years. We feel that there is no relation between carcinoma of the pancreas and either diabetes or hyperinsulinism.

Ten of our patients exhibited the Bard-Pick syndrome, i.e., progressive jaundice with no remissions, distention of the gallbladder, absence of hepatic enlargement, subnormal temperature and rapid cachexia and emaciation. All cases showed a secondary anemia due to nutritional disturbance. Stool analysis in five cases showed an absence of bile and presence of occult blood. In one case, the presence of undigested food in the stool was owing to a fistula between the jejunum and the transverse colon.

MARYLAND

Differential Diagnosis

Since the diagnosis of primary carcinoma of the pancreas is largely by exclusion, the differential diagnosis assumes considerable importance. This condition is most apt to be confused with stone in the common duct. However, we have a rather reliable test, the Watson test, for ruling out the stone in the common duct. With stone, a little bile always enters the intestinal tract; more, in fact, than when the symptom of jaundice is due to neoplasm in the biliary passages. The outflow of bile can be measured by urobilinogen estimation. In cases of jaundice due to stone in the common duct, Watson has reported, the amount of urobilinogen in the feces is in no instance less than 10 mgm. per day, and usually more. Hence, if the Watson test reveals more than 10 mgm. of urobilinogen, in a suspected case of carcinoma of the pancreas, we can, with some certainty, rule out the possibility of carcinoma. At Ancker Hospital, the Watson test has proved accurate in more than 90 per cent of twenty-eight cases of biliary obstruction.

Another diagnostic point in ruling out stone in the common duct is that the patients with stone generally suffer more acute pain.

Other conditions from which primary carcinoma of the pancreas must usually be differentiated are: (1) benign stricture of the common duct; (2) carcinoma of the gallbladder or bile duct; (3) carcinoma of the duodenum and ampulla of Vater; (4) chronic pancreatitis with sclerosis of the gland; (5) biliary cirrhosis; and (6) acute catarrhal jaundice.

The differentiating points are as follows:

In benign stricture of the common duct, we usually get a history of some operative procedure in this region and the symptoms are of longer duration.

Chronic pancreatitis, with sclerosis of the gland, is also generally of longer duration. It is more common in females, and may produce a fever instead of the subnormal temperature common with carcinoma of the pancreas. Acute catarrhal jaundice may also produce chills and fever. It usually occurs in younger people.

Biliary cirrhosis is commonly a more chronic ailment than primary carcinoma of the pancreas.

With carcinoma of the gallbladder or bile ducts, complete blocking of the bile flow usually occurs, and probably earlier. With carcinoma of the duodenum and ampulla of Vater, x-ray examination may be helpful. However, all the carcinomas in sites adjacent to the pancreas are exceedingly difficult to differentiate.

Some help may be had by applying Courvoisier's law when considering patients with jaundice: If the gallbladder is distended, carcinoma of the pancreas or common duct is the cause. If the gallbladder is contracted, it is due to stone in the common duct. Lewis states that Courvoisier's law is correct in about 80 per cent of the cases.

X-ray Examinations

Negative findings in the stomach and duodenum are exceedingly valuable in excluding these organs as sites of the cancer process. Of our thirty-nine cases, however, only seventeen were submitted to x-ray examination. In five cases there was an extrinsic stomach mass; in two, a cascade stomach; in one, a jejunal colic fistula; and in one, a widening of the duodenal ring due to an extrinsic mass.

Discussing the x-ray findings in carcinoma of the pancreas, W. H. Dixon states that carcinoma of the pancreas can often be diagnosed by observing the pressure of an extrinsic mass on the duodenum, pylorus or cardiac and of the stomach. Harrison states that carcinoma of the head of the pancreas causes stenosis or narrowing and displacement of the duodenum and an increase of the duodenal loop. Tumors of the pancreas have been visualized by means of pneumoperitoneum and lateral pictures.

Prognosis

The prognosis in primary carcinoma of the pancreas is exceedingly grave. However, it is not absolutely hopeless. We can report one patient, who underwent cholecystograstrostomy, who is alive and well four years after the operation.

Walters states that 15 per cent of 113 patients with tumor in the region of the head of the pancreas causing biliary obstruction were alive three years after operation. W. J. Mayo records the case of an old lady who lived six years after cholecystogastrostomy for biliary obstruction due to a mass at the head of the pancreas.

Most surgery for carcinoma of the pancreas, however, must be considered frankly palliative or exploratory. Moynihan said that all cases of obstructive jaundice are entitled to an exploratory laparotomy. Lewis has further pointed out that in all operations on the gallbladder and bile ducts, the pancreas should be palpated, for the reason that if there is any suspicion of carcinoma of the pancreas, the gallbladder should not be removed. Presence of the gallbladder is one of the most important palliative factors in the treatment of carcinoma of the pancreas. In Lewis's cases the average duration of life after operation was from six to eight months, but during this period the patients were free from their previously marked jaundice and pruritus.

With carcinoma of the pancreas, metastasis takes place early by direct extension to: (1) the tissues adjacent to the pancreas; (2) to the regional lymph nodes; and (3) through the blood stream.

Of the thirty-four cases in our series which came to autopsy, twenty showed metastases to the liver, eighteen to the regional lymph nodes, twelve to the peritoneum, one to the gallbladder, four to the adrenals, two to the stomach, one to the kidney, one to the spleen, five to the small intestine, and one to the thyroid.

Treatment

Though x-ray and radium are sometimes beneficial, surgical intervention is generally the best palliative means. Cholecystoduodenostomy and cholecystojejunostomy are the operations of choice. Lahey recommends cholecystojejunostomy.

In addition to cholecystogastrostomy, the other possible operations are cholecystoenterostomy, cholecystostomy, and radical excision. Three cases have been reported in which the pancreas was completely removed without intervention of diabetes. However, in these three cases recurrence and death occurred within six months. Cholecystostomy is inadvisable because of the loss of bile needed for emulsifying fats. This bile loss prompts a more rapid decline of the patient. With cholecystocolostomy, there is the danger of a rapidly ascending infection of the gallbladder and bile ducts.

The best incision for complete exploration of the pancreas is a transverse incision above the umbilicus, cutting both recti muscles. The gastrocolic omentum is divided, thus exposing the entire gland.

Sauve and Desjardins developed a technic for partial and total pancreatectomy. The operation consists of: (1) anastomosis of the gallbladder or common duct to the stomach; (2) gastroenterostomy; (3) resection of the head of the pancreas and duodenum; (4) implantation of the remainder of the pancreas into the jejunum.

Operations were performed on nineteen of the thirty-nine cases in our series as follows: exploratory laparotomy, 5; cholecystogastrostomy, 4; cholecystostomy, 3; cholecystectomy, 1; cholecystoduodenostomy, 3; choledochotomy, 1; cholecystocolostomy, 1; posterior gastroenterostomy for duodenal obstruction due to large pancreatic mass, 1.

Summary and Conclusions

A series of thirty-nine cases of primary carcinoma of the pancreas, proved by autopsy or operation, have been reviewed.

Primary carcinoma of the pancreas is most common in the fifth and sixth decades; the average age of incidence in this series was sixty-one years. It is more common in males than in females, the ratio in this series being 2.5 to 1. The head of the pancreas is most commonly involved; only the head was involved in almost 60 per cent of the cases in this series.

The diagnosis of primary carcinoma of the pancreas is largely by exclusion. Most commonly it must be differentiated from stone in the common duct. For this purpose, the Watson test is very useful.

Negative x-ray findings in the stomach and duodenum are also of great value as diagnostic aids.

Jaundice should not be considered a cardinal symptom. At least four and possibly seven cases in this series had no jaundice and no involvement of the common duct.

The prognosis is grave but by no means hopeless. Surgical intervention is the best palliative means. Cholecystoduodenostomy and cholecystojejunostomy are the operations of choice.

POSTURAL HYPOTENSION*

Hourly and Daily Blood Pressure Variations

HARRY C. BROWNE, M.D., and BAYARD T. HORTON, M.D.

Rochester, Minnesota

A PHYSICAL examination is never complete until the blood pressure has been recorded with the patient in the recumbent as well as in the erect posture. Failure to carry out this simple procedure results in many patients going from physician to physician looking for help because of dizzy spells and weakness, and seldom finding the help. Hourly and daily records of blood pressure in such a case tell a graphic story, but thus far we have not seen such a record in print. The following report of a case, with accompanying comment and illustration, is presented to emphasize the importance of such a case in everyday practice and to show graphically the variations in blood pressure.

Report of Case

A white man, aged seventy years, a retired school teacher and farmer, entered The Mayo Clinic, September 15, 1938, complaining of spells of weakness and dizziness. The family history was essentially negative. The man always had been asthenic, although his general health had been exceptionally good. He had had influenza in 1918 and appendectomy had been performed for recurrent appendicitis in 1914.

He first had noticed the dizziness and weakness five years before we saw him. These symptoms had appeared following an attack of what had been termed "mucous colitis" which had been characterized only by an excess of mucus in the stools. The patient noted the weakness especially in the morning, after rising, and the dizziness on standing after he had been recumbent or sitting for some time. He experienced actual syncope at times. The attacks had come at occasional intervals until the year before his coming to the clinic. By the time of his examination they were occurring many times a day. Frequently, while walking, he would have to bend over to rid himself of dizziness or he would be obliged to sit or recline. These measures invariably brought relief. He was more uncomfortable and suffered more attacks during the cold seasons than at other times.

The man complained, in addition, of nocturia, and stated that he excreted a larger amount of urine during the night than during the day. Since December, 1937, he had been troubled by a postnasal drip and occasionally he easily expectorated blood-tinged mucus. He had no chronic cough or other respiratory symptoms. All his life he had been constipated, but aside from this and the attack of mucous colitis there were no other gastro-intestinal symptoms. He never had noticed any abnormalities of sweating; he complained of mild paresthesia in the fingers and toes.

On physical examination the patient appeared at least ten years younger than his actual age. There was no graying of the hair and no tendency to baldness. The skin was soft and senile changes were few. The tonsils were chronically infected. Nothing could be found in the upper respiratory passages to account for the blood-tinged mucus. There were a minimal amount of arteriosclerosis and a few vitreous opacities in the ocular fundi. Periapical dental infection was graded 2 and pyorrhea alveolaris was graded 1, on a scale in which 1 indicates minimal and 4 extreme difficulty. The carotid sinus reflex was not hyperactive. Examination of the thorax revealed only senile emphysema and a soft, apical, systolic murmur. The abdomen appeared to be normal with the exception that muscular tone was poor. The prostate gland was enlarged (grade 1) and prostatitis was graded 1. There was no residual urine. There were moderate sclerosis and tortuosity of the peripheral arteries. Neurologic examination revealed only slight impairment of vibratory sensation.

With the coöperation of the patient some special observations were made.

Observation 1.—The patient was hospitalized and hourly readings of blood pressure were taken while he was recumbent and erect (Figs. 1 and 2). The mean pressures with the patient supine were 140 mm. of mercury systolic and 90 diastolic and with the patient standing 65 systolic and 35 diastolic. The maximal variation in pulse rate was represented by the difference between a rate of 66 beats per minute when the patient was recumbent and 74 beats per minute when he was erect. In figures 1 and 2 it is seen that the blood pressure, while the patient was standing, followed a relatively level curve, without pronounced variations, but that while he was recumbent it exhibited definite fluctuations and at times was actually of hypertensive type.

Observation 2.—The patient was placed on a tilting table at an angle of 45 degrees, head uppermost, and was given, at intervals of three minutes, intravenous injections of 12.5 mg. of ephedrine sulfate totaling 100 mg. At the beginning of the observation his blood pressure was 70 systolic and 60 diastolic and his pulse rate was 60. At the end, his blood pressure was 84 systolic and 60 diastolic and his pulse rate was 100; he could stand and walk without dizziness or weakness.

---

*From The Mayo Foundation (Browne) and the Division of Medicine (Horton), The Mayo Clinic, Rochester, Minnesota.

Observation 3.—The man was placed in a baker to determine in what areas sweating would appear.[11] Sweat was found everywhere on the body except for a small area on the inner aspect of each leg.

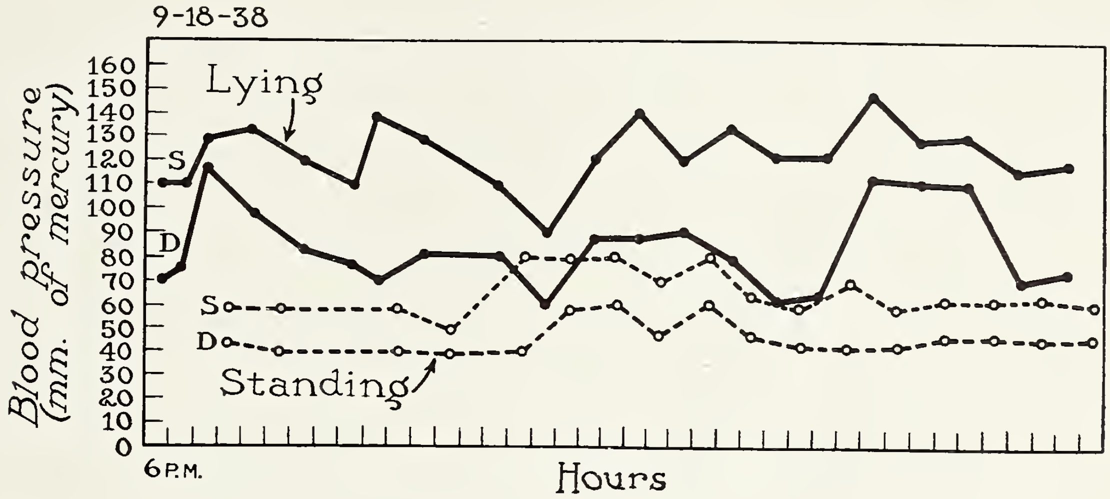

Fig. 1. Hourly readings of blood pressure over a period of approximately forty consecutive hours. Solid lines indicate blood pressure with patient recumbent and dotted lines, with patient standing. S indicates systolic and D, diastolic.

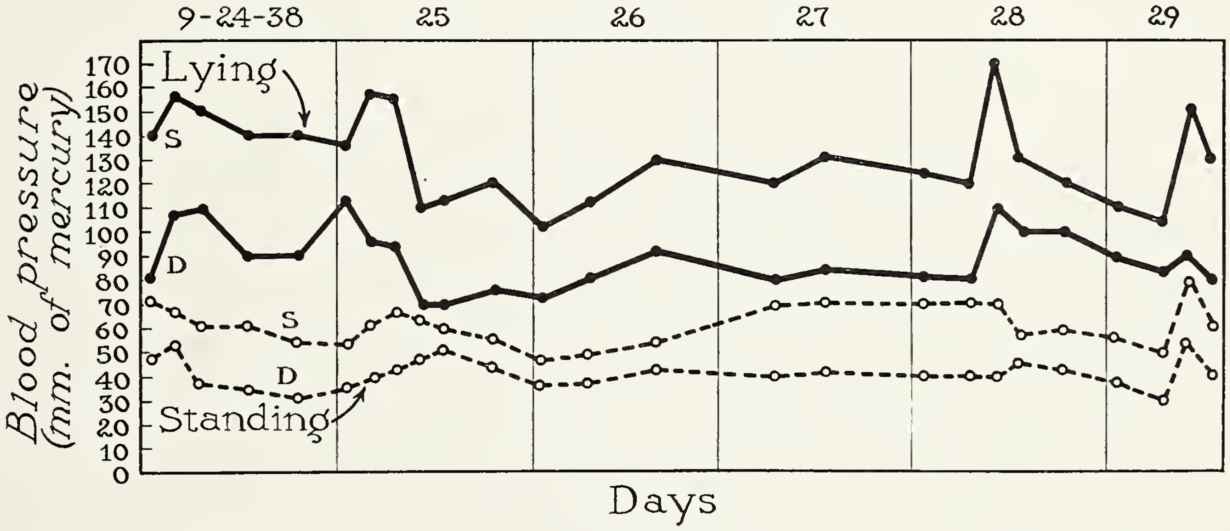

Fig. 2. Observations on blood pressure plotted as in Figure 1, but at less frequent intervals, over a period of approximately six days.

Observation 4.—For several days all urine excreted during the day (7 a.m. to 7 p.m.) was collected in one container and all that excreted during the night (7 p.m. to 7 a.m.) in another. The average diurnal output was 500 c.c. and the average nocturnal output 900 c.c.

Observation 5.—A tight abdominal binder was applied whenever the patient walked; this reduced the tendency toward syncope. When the patient was standing and the binder was removed he experienced marked giddiness and weakness.

Laboratory Examinations.—Results of most of the laboratory tests were negative. In terms of milligrams per 100 c.c., results of blood chemical examinations were as follows: urea nitrogen, 42 mg.; serum sulfates, 4.1; fasting blood sugar, 100; chlorides, 585; sodium, 308; potassium, 17.6; phosphorus, 2.4; calcium, 10. The basal metabolic rate was +6. Roentgenograms of the thorax were negative.

Treatment.—Various schedules of medication were tried, in which preparations of ephedrine, benzedrine and paredrine were administered. Ephedrine sulfate and paredrine hydrobromide seemed fairly satisfactory in overcoming the weakness and syncope but produced little change in the blood pressure. The aim of treatment in this type of case is to eliminate the disagreeable subjective sensations rather than to raise the blood pressure to normal.

For about two weeks (Table I) the daily schedule included administration of both ephedrine sulfate and paredrine hydrobromide and the patient noted improvement of his condition. Later (Table I), administration of paredrine hydrobromide was discontinued and ephedrine sulfate only was used. This later schedule was somewhat more satisfactory than the one that was followed during the first two weeks.

On dismissal, October 12, 1938, the patient's blood pressures, when he was sitting, were 100 systolic and 70 diastolic; when he was standing, 76 systolic and 50 diastolic and when he was recumbent, 142 systolic and 90 diastolic. Subjectively his condition was greatly improved.

Comment

Postural, or orthostatic, hypotension was first described as a clinical entity in 1925 by Brad-

bury and Eggleston when they reported three cases. Prior to that time, for many years it had been known that sometimes blood pressure changed markedly when posture changed. As early as 1905, Crampton showed that the pulse and blood pressure of man varied with change in posture.[4,5] Mortensen, in 1923, attributed the change in blood pressure to myocardial response rather than to vasomotor instability. Ghrist and Brown in 1928 first successfully used ephedrine in treating these patients. Korns and Randall employed benzedrine and the related compound, paredrine. They noted an increased pressor effect of the latter drug compared with the former and a decreased stimulating action on the central nervous system. From time to time additional cases have been reported[1, 2, 6, 12] in most of which the following phenomena have been exhibited: (1) a pronounced drop in systolic and diastolic blood pressure, and syncopal attacks, on change from the recumbent to the upright position; (2) no increase in pulse rate with this drop in blood pressure; (3) anhidrosis or decreased sweating and inability to stand hot weather; (4) excretion of more urine at night than during the day; (5) a false appearance of youth; (6) a slightly low basal metabolic rate; (7) signs of slight changes in the nervous system; (8) concentration of blood urea at the upper limit of normal.

Postural hypotension is not a disease but is an expression of inadequate control of the arterial system which may be associated with numerous diseases. As to its underlying cause, there is still dispute. In their original article, Bradbury and Eggleston attributed the condition to deficiency or paralysis of the myoneural junctions. Ghrist and Brown brought forth the hypothesis that the splanchnic vessels lacked resistance to shifts in blood mass and that vagal regulation of the cardiac rate with alterations in blood pressure was diminished or absent. MacWilliam expressed the belief that the difficulty lay in the lower extremities themselves, for he said there was little change in splanchnic blood mass with the sitting and standing posture; the only factor which changed was the position of the limbs. Crampton declared that, in the sitting posture the splanchnic circulation was maintained within limits by the support afforded by the limbs being flexed on the trunk. About as many different hypotheses have been propounded as the number of cases reported. The conclusion is that the vasomotor system plays the predominant rôle in the decrease of blood pressure in the standing position.

In the case reported here not all of the characteristics mentioned in a preceding paragraph were found. There were, of course, the marked fall in blood pressure, the syncopal attacks and the slow, unchanging pulse rate. Intravenous injection of ephedrine, however, caused acceleration of the pulse as has been pointed out (observation 2) and this showed that the normal function of the cardiac accelerator mechanism with change in blood pressure had not vanished. Our patient did not exhibit abnormal sweating and that he did not was an index of normal sympathetic control. Instead of inability to stand hot weather he suffered most during cold seasons. One of his most bothersome symptoms was excessive nocturnal urination. He possessed the false appearance of youth but not the characteristically low basal metabolic rate. The diminished vibratory sensation may have been a natural senile change and it was the only sign we could place in the category of slight changes in the nervous system. The concentration of blood urea was in the higher limits of normal as would be expected. It is interesting to compare the fluctuating curve this patient's blood pressure presented when he was recumbent with the relatively flat curve obtained when he was erect.

THE VALUE OF PERSISTENCE IN THE TREATMENT OF THROMBO-ANGIITIS OBLITERANS: REPORT OF TWO ILLUSTRATIVE CASES*

ERIC E. WOLLAEGER, M.D., E. V. ALLEN, M.D., and RALPH K. GHORMLEY, M.D.

**Section on Orthopedic Surgery, The Mayo Clinic
Rochester, Minnesota**

THE pessimistic attitude relative to the outlook for patients with thrombo-angiitis obliterans has gradually changed to a more optimistic one. That much can be accomplished for such patients is more apparent as experience in medical, neurosurgical and conservative orthopedic treatment of this condition accumulates. This change in attitude has resulted from development of logical methods of treatment and the gradual recognition that persistence is most important. In considering treatment of patients with thrombo-angiitis obliterans with gangrenous lesions, ulcers or pain while the limb is at rest, both patient and physician must be thoroughly imbued with the idea that treatment over a comparatively long period of time is essential if the best results are to be accomplished. It is sometimes well to point out to a patient that many diseases, such as tuberculosis, for example, require treatment for months and that thrombo-angiitis may be as demanding of time. When this situation is discussed with a patient with thrombo-angiitis obliterans soon after treatment is begun, he is easily reconciled to slow progress, a state of mind which in itself seems to hasten improvement. It is the purpose of this report to stress the importance of persistent treatment.

Report of Cases

Case 1.—A twenty-seven year old salesman of Scotch-English descent entered The Mayo Clinic on February 1, 1937, because of painful ulcerations on the first, second and third left toes, which had been present for one month.

There was no family history of vascular disease except that his father had had hypertension. Six years before admission the patient had frozen his feet but recovery had occurred promptly and there had been no residual symptoms. He had begun to smoke cigarettes at the age of seventeen and he had consumed between twenty and forty of them a day since that time. His past history was otherwise irrelevant.

Two and a half years before admission the patient noticed several red tender lumps along the veins of the lower part of both legs, which disappeared in about a month.

Two and a half months before admission, while the patient was recovering from an attack of "influenza," there was a sudden onset at rest of marked numbness, coldness, pallor and pain involving the left foot. These symptoms were so severe that he was taken to a hospital, where he was treated by the application of hot and cold packs, intravenous injection of a solution of sodium chloride and some intramuscular injections. The condition of his foot gradually improved so that one month after the onset of the symptoms he was once more walking about. At this time he experienced a similar episode of sudden onset of pain and numbness in his left foot, the distal half of which became cold and white. A few days later a Leriche operation (periarterial sympathectomy) was performed on his left femoral artery. One month before admission, the left first, second and third toes became darkly discolored and ulceration of them occurred.

During the one and a half months prior to admission the gangrenous toes were affected with pain, which was severe enough to prevent sleep and which was partially relieved by allowing the left foot to hang over the edge of the bed. The patient's appetite also was diminished so that he lost 20 pounds (9 kg.) in weight.

TABLE I. RESPONSE OF TEMPERATURE OF SKIN OF TOES AND FINGER OF A PATIENT SUFFERING FROM THROMBO-ANGIITIS OBLITERANS TO INTRAVENOUS INJECTION OF TYPHOID VACCINE

	Temperature*				
	Mouth	Toes			Finger
		Right first	Right fourth	Left fourth	Right third
Before injection	99.5 (37.5)	85.8 (29.9)	85.5 (29.7)	83.7 (28.7)	87.1 (30.6)
After injection	101.3 (38.5)	97.3 (36.3)	96.6 (35.9)	88.9 (31.6)	99.1 (37.3)

*In degrees Fahrenheit; figures in parentheses are in degrees Centigrade.

On examination at The Mayo Clinic the patient was found to weigh 140 pounds (64 kg.). The oral temperature was 97.6° F. (36.4° C.), the pulse rate 112 beats per minute and the blood pressure was 115 mm. of mercury systolic and 90 diastolic. The results of the general examination, exclusive of the extremities, were negative except for tachycardia and moderately enlarged tonsils.

The muscles of the entire left leg were somewhat atrophied, weak and flabby. The entire left second toe was black, shrunken and crusted and there were similar changes on the dorsum, tip and lateral surface of the great toe and on the dorsum at the base of the third toe. The distal half of the nail of the left first toe had been removed (Fig. 1). Pulsations were normal in radial, ulnar, femoral, popliteal and posterior tibial arteries bilaterally. Pulsations could not be felt in the dorsalis pedis arteries bilaterally. There were no unusual changes in color of the skin of the hands and right foot as a result of elevation or dependency. Color changes dependent on posture of the left foot could not be determined because of staining of the skin with mercurochrome. The response of the temperature of the skin of the toes to fever induced artificially by the intravenous injection of typhoid vaccine is shown in Table I. This study indicated marked impairment of circulation to the left fourth toe. Studies of the temperature of the skin of the left first, second and third toes were not made because attachment of the thermocouple junctions to them caused pain.

Laboratory studies: The results of routine laboratory studies, including determination of hemoglobin, enumeration of erythrocytes and leukocytes in the blood, a serologic test for syphilis and differential leukocyte count, were essentially normal. On repeated urinalyses traces of albumin were found and in several samples there was slight reduction of Benedict's solution. The blood sugar was 72 mg. per 100 c.c. of blood. Sedimentation of the blood was 17 mm. in an hour. Roentgenographic examination of the lungs and left foot gave negative results.

A diagnosis of thrombo-angiitis obliterans with two episodes of sudden arterial occlusion was made.

The patient was treated in the hospital. Smoking was prohibited. Most of the time the patient rested in bed and weight-bearing on the left foot was carefully avoided. Radiant heat was applied to the feet by means of carbon filament bulbs in a cradle. The temperature of the air about the feet was maintained at about 90° F. (32.2° C.). The left foot was soaked several times daily in a warmed solution of boric acid or chloramine. Intermittent suction and pressure could not be employed because this procedure increased the pain. On the day following admission to the hospital, fever was induced artificially by injecting intravenously a vaccine containing killed typhoid and paratyphoid A and B organisms. Pain was accentuated as a result of this procedure but it was considerably diminished the following day. Subsequent intravenous injections of vaccine were given at intervals of two to eight days and the patient received twenty-nine of them during the five months he was in the hospital. During this same period he received passive vascular exercises on the Sanders bed for 308 hours. Anodynes and sedatives were administered to relieve pain and induce sleep. During a period of five months he received the following amounts of drugs; morphine sulfate 9.1 grains (0.59 gm.), dilaudid 2.2 grains (0.14 gm.), codeine sulfate 233 grains (15.1 gm.), acetylsalicylic acid 1,580 grains (102.4 gm.), phenobarbital 139 grains (9.0 gm.), sodium amytal 39 grains (2.5 gm.) and pentobarbital sodium 71.5 grains (4.63 gm).

On this regime progress was slow and indeed for a considerable time was doubtful. The patient continued to have a great deal of pain so that fairly large amounts of opiates were required—especially during fever induced by intravenously injected vaccine. It was thought wise to defer any operative removal of the gangrenous areas until such a time as complete demarcation had occurred and the blood supply to the surrounding tissue had been developed as much as possible, or even to wait until spontaneous amputation should occur. Accordingly some other method for the relief of pain had to be employed. Three weeks after admission, under infiltration anesthesia the left superficial and deep peroneal nerves were resected in the lower leg and the left posterior tibial nerve was crushed. After this operation there was reduction of pain in the left foot of about 50 per cent, although partial sensation remained in the distribution of the posterior tibial nerve on the plantar surface of the foot.

Two and a half months after admission a second operation was performed. Under pentothal sodium anesthesia the second left toe was amputated at the line of demarcation, that is, through the metatarsophalangeal joint, and the first phalanx of the great toe, which was projecting into the wound, was completely removed, as was the nail of this toe, under which considerable pus had accumulated.

Subsequent healing was slow but progressive until the time of the patient's discharge from the hospital three and a half months after admission, at which time small areas of granulation tissue were present at the sites of removal of the second toe and of the first toenail and at the area in which the phalanx of the first toe had been removed (Fig. 2). The patient returned to the hospital in a week, however, because of ulceration in these areas brought on by walking and weight-bearing. A month later (five months after the first hospital admission) he was again discharged, at which time healing was complete.

In a letter received from the patient four months after dismissal he stated that he was enjoying good health and leading an active life with no recurrence of ulceration or return of pain. He had gained 45 pounds (20 kg.) in weight. Thirteen months after dismissal the patient stated he was entirely well.

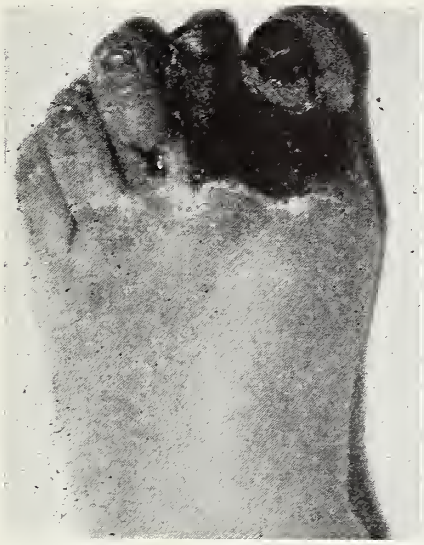

Fig. 1. Thrombo-angiitis obliterans. Appearance of foot at time of admission of patient to hospital.

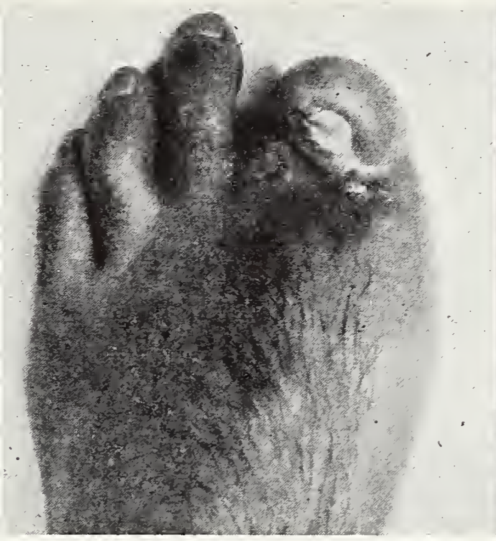

Fig. 2. Thrombo-angiitis obliterans. Same extremity as pictured in Figure 1 but after treatment.

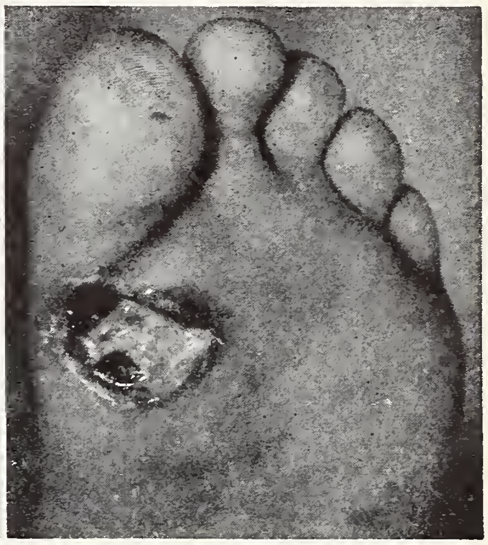

Fig. 3. Thrombo-angiitis obliterans, with gangrenous ulcer on plantar surface of foot.

There can be no valid criticism of the diagnosis of thrombo-angiitis obliterans in this case. The patient had had superficial phlebitis, which, in conjunction with occlusive arterial disease, is almost pathognomonic of thrombo-angiitis obliterans. Sudden arterial occlusive disease occurs commonly in this condition. In a study of 225 cases, Kvale and one of us (Allen) found that sudden occlusion occurred in the course of well established thrombo-angiitis obliterans in fifteen cases, or 7 per cent, and as an original event in eleven cases, or 5 per cent, of the cases. This case which we have presented seems clearly exemplary of the latter situation. The fortunate outcome can be attributed to no single method of treatment, for many methods persistently carried out seem clearly responsible.

Case 2.—The patient, a thirty-five-year-old oil field worker of Irish descent, entered The Mayo Clinic on January 30, 1937, because of a painful ulcer on the medial aspect of the ball of the left foot, which had been present for one month.

Family and past histories were irrelevant except that the patient had smoked one package of cigarettes a day for many years.

In the fall of 1934, about two years before admission, the patient developed a red, painful nodule on the radial aspect of the left lower arm, which seemed to migrate around the arm and also up its length to the elbow. Redness and pain were intermittent and there was no fever. In three or four months the nodule disappeared entirely.

One year before admission the patient began to have claudicatory pain in the arches of the feet. Six months later similar pains began in the calves of his legs, allowing him to walk only a block or so before he had to stop and rest.

During the year previous to admission the patient noticed spots of cyanosis on the fingers of the left hand (most marked on the third and fifth fingers) and on both feet. These patches were noticeable only on exposure to cold and disappeared with the application of warmth. Pallor of the fingers and toes was present when these parts were elevated, but there was no pain while they were at rest. On two occasions the patient had developed small ulcers along the sides of the nails on the third and fifth fingers, each requiring several weeks to heal.

TABLE II. GRADE OF PULSATION IN EXTREMITAL ARTERIES OF A PATIENT SUFFERING FROM THROMBO-ANGIITIS OBLITERANS

Artery	Pulsations	
	Right	Left
Radial	4	0
Ulnar	4	0*
Femoral	3 to 4	2 to 3
Popliteal	2	0
Posterior tibial	0	0
Dorsalis pedis	0	0

Grade 0—No pulsation.
Grade 4—Normal pulsation.

---

*Though pulsations were absent in the left ulnar artery, there was present a fairly good sized collateral artery on the dorsum of the ulnar side of the lower arm in which pulsations were graded 2.

Two months before admission the patient noticed a small blister on the medial aspect of the ball of the left foot. This increased in size and was accompanied by so much pain and swelling of the foot that he was forced to take to his bed a month later. The blister was opened and trimmed by his physician, but in spite of this and other treatment, including intermittent suction and pressure, injections of tissue extract and

TABLE III. RESPONSE OF TEMPERATURE OF SKIN OF TOES AND FINGER OF A PATIENT SUFFERING FROM THROMBO-ANGIITIS OBLITERANS TO INTRAVENOUS INJECTION OF TYPHOID VACCINE

	Temperature*					
	Mouth	Toes				Finger
		Right first	Right fourth	Left first	Left fourth	Left fifth
Before injection	99.5 (37.5)	80.2 (26.8)	81.0 (27.2)	83.5 (28.6)	81.9 (27.7)	83.3 (28.5)
After injection	102.9 (39.4)	85.5 (29.7)	84.2 (29.0)	86.9 (30.5)	84.9 (29.4)	97.5 (36.4)

*In degrees Fahrenheit; figures in parentheses are in degrees Centigrade.

insulin and two injections of typhoid vaccine, the ulcer failed to heal. The patient continued to smoke most of the time during his illness.

On examination at the time of admission the patient was well nourished. The oral temperature was 98.2° F. (36.8° C.). The pulse rate was 80 beats per minute and the blood pressure was 130 mm. of mercury systolic and 80 diastolic. The results of a general physical examination were essentially negative except for the extremities. Over the medial aspect of the first metatarsophalangeal joint of the left foot was a traumatic, infected, gangrenous ulcer, 3 cm. in diameter and 1.5 cm. deep (Fig. 3). The ulcer and the surrounding infected area were intensely tender and the left foot was swollen, grade 2, on a basis of 1 to 4. There was considerable pain in the region of the ulcer while the foot was at rest, which prevented the patient from keeping his left leg in bed and caused him to allow it to hang over the edge of the bed most of the time.

Circulation in both feet as well as in the left hand was appreciably impaired as shown by abnormal pallor in the elevated position and abnormal rubor in the dependent position. Pulsations in many of the main arteries of the extremities were impaired as demonstrated in Table II.

The response of the temperature of the skin of the toes to fever artificially induced by the intravenous injection of typhoid vaccine is shown in Table III. This study indicated marked impairment of circulation to the toes of both feet. Collateral circulation to the left hand was adequate.

Routine laboratory studies, including numerous urinalyses, determination of the blood hemoglobin and enumeration of the erythrocytes and leukocytes in the blood, gave normal results. Quantitative determinations of blood lipoids resulted as follows: Total fats, 726 mg. per 100 c.c.; cholesterol, 252 mg. per 100 c.c., and fatty acids, 474 mg. per 100 c.c. Roentgenographic examination of the lungs and of the left foot gave negative results.

A diagnosis of thrombo-angiitis obliterans was made.

The patient was treated in the hospital, where he rested in bed most of the time, avoiding all weight-bearing on the ulcerated foot. His feet were protected by a wooden cradle in which radiant heat was applied to them by means of carbon filament bulbs, which maintained the air about his feet at a temperature of about 90° F. (32.2° C.). The left foot was soaked several times a day in a warmed solution of boric acid, chloramine or potassium permanganate. Zinc peroxide paste was applied to the healing ulcer daily for several weeks during the midportion of his stay in the hospital. On the day following admission to the hospital, fever was induced artificially by the intravenous injection of a vaccine containing typhoid and paratyphoid A and B organisms. After an initial accentuation of pain this procedure resulted in a marked relief from pain on the following day. Fifteen subsequent intravenous injections of vaccine were made at two to eight day intervals during the two months the patient was in the hospital. During this period of time he received, daily, passive vascular exercises on the Sanders bed for a total of forty-four hours. Intermittent suction and pressure also were applied to the left leg daily for a total of eighty-two hours. Smoking was strictly prohibited throughout treatment. Moderate amounts of anodynes and sedatives were administered for the relief of pain and the induction of sleep.

From the beginning the patient's progress was slow because of the great size and depth of the ulcer on his foot, which gradually became filled with granulation tissue and finally was covered by epithelium. Even at the time of his dismissal, two months after admission, there was a fairly deep depression at the site of the former ulcer. In a letter received three months after dismissal the patient stated that this depression was almost entirely filled in and that he had been working for two months, though he could not stand on his feet for any great length of time.

A second letter, eight months after dismissal, stated that the patient was on his feet eight hours a day without pain except from walking, which brought on claudication at three blocks. There was still slight tenderness to pressure over the site of the old ulcer. The color of his feet was said to be better.*

Two important lessons can be gained from a study of this case report. Minor surgical procedures are frequently ill advised, for they may cause gangrene or gangrenous ulcers in many cases. Barker's study showed that such undesired results had followed injudicious surgical procedures in a third of the cases of thrombo-angiitis obliterans with gangrenous lesions. The prospect for recovery when gangrene or gangrenous ulcers are present is substantially less than when they are absent. Injudicious surgical procedures consist chiefly in removal of the toenails and corns or of calluses, and in incision for suspected abscess. We recommend strongly that no local surgical procedures be performed in any case until blood supply has been proved adequate or until the surgeon has carefully considered the ill effects which may follow such procedures when blood supply is diminished. The second lesson is that lesions which appear at first glance to be severe enough to justify amputation may disappear as a result of intensive medical treatment.

---

*Since this paper was written the patient writes eighteen months after dismissal that the condition of his feet is excellent. There are no ulcers of the feet or pain except intermittent claudication when walking a considerable distance. The nails are growing.

Comment

The two cases reported emphasize that gangrenous lesions in thrombo-angiitis obliterans do not always necessitate amputation. On the contrary, intensive medical treatment may cause healing and restoration of an extremity to useful function. An outline of the treatment of thrombo-angiitis obliterans is beyond the scope of this paper. It has been presented adequately elsewhere. Treatment is seldom uniform in type but usually is an individual affair, varying greatly from case to case, and may necessitate close coöperation of internist, orthopedist and neurosurgeon. In this presentation we have emphasized the importance of persistence of medical treatment in many cases. It is impossible to state precisely when medical treatment should be abandoned for amputation, as criteria for amputation vary greatly from case to case. In general, severe pain which cannot be controlled adequately by medical or neurosurgical means, or gangrenous lesions which do not respond to intensive medical treatment over a considerable period of time, require amputation.

The physician dealing with many patients with thrombo-angiitis obliterans sees two types of cases for which decision relative to treatment is not difficult. There are cases for which prompt amputation is advisable and cases for which amputation need not be considered. For the latter cases medical treatment and perhaps sympathectomy are clearly indicated. In a third group of cases the question arises at once whether or not amputation is advisable. In such circumstances it is best to treat patients conservatively for a minimum period of several weeks. If unsatisfactory progress results from this regime, then amputation may be considered. If the treatment causes improvement, it may be continued.

The physician may object at once that thrombo-angiitis obliterans is a chronic disease and that healing of lesions such as those described does not necessarily mean cessation of the disease. He may point out that amputation may be advisable eventually and that there is little reason for deferring the time when such treatment is necessary. Such an attitude prompts decision to amputate limbs as soon as the diagnosis of thrombo-angiitis obliterans is made. Fortunately, the poor logic of this is apparent, for many patients with thrombo-angiitis obliterans have two fairly normally functioning legs all their lives; many others keep one normally functioning leg.

Other physicians may point out that the cost of conservative treatment over a long period of time may be great. It is almost always good policy to discuss the situation frankly with the patient. If he desires a trial of conservative treatment, it seems to us he should have it. If such treatment impresses him as too costly and too uncertain of producing good results, amputation may be advisable. Too many factors influence a patient to allow advising him dogmatically. The physician should not allow a poorly founded attitude of pessimism on his part to influence the patient to accept amputation when it may not be necessary. We agree that some patients are treated conservatively too long but in many instances "too poor" treatment is mistaken for "too long" treatment. We cannot agree that the cost of an intensive but conservative program for a few weeks is too great if there is a chance of producing healing of gangrenous lesions and quiescence of the disease. We believe that the incidence of amputation for thrombo-angiitis obliterans can be reduced sharply. Earlier recognition, better conservative treatment and less haste to amputate in many cases are very desirable. Much can be accomplished in producing results which amply justify conservatism. We have presented two illustrative cases to support this contention.

◆ CASE REPORT ◆

PICROTOXIN TREATMENT OF BARBITURATE INTOXICATION

A. E. Cardle, M.D., and Wayne S. Hagen, M.D.
Minneapolis, Minnesota

THE recent report of the Council on Pharmacy and Chemistry of the American Medical Association[1] gives the present status of the use of picrotoxin in the treatment of poisoning by the barbiturates. The following case is reported because it is believed to have demonstrated to the authors the efficacy of the use of this drug and also because it illustrates a clinical example of the picrotoxin-barbiturate antagonism or the antidotal action of picrotoxin in barbiturate intoxication.

Picrotoxin is a bitter neutral principle prepared from Anamirta paniculata (Cocculus indicus). It stimulates the motor and inhibitory centers in the medulla, especially the vagus and respiratory centers. Picrotoxin ($C_{30}H_{34}O_{13}$) may be broken up into Picrotoxinin ($C_{15}H_{16}O_6$) and Picrotin ($C_{15}H_{18}O_7$); is soluble in eight parts of alcohol or 240 parts of water. Koppanyi et al[6] found that it had a distinct awakening or cortical effect aside from its medullary stimulating action. The studies of Maloney, Fitch and Tatum[4] in 1931 called attention to the antidotal action of picrotoxin in the treatment of barbiturate poisoning. Subsequent reports by these same authors[5] established a clinical basis for the use of this drug and the report of four cases by Kohn, Platt and Saltman[3] and an additional report by Bleckwenn and Masten[2] of six cases have added further proof of the clinical value of picrotoxin as an antidotal or antagonistic agent against the toxic effects of overdoses of the barbitals.

Case Report

A white woman, aged twenty-four, weighing 108 pounds, sixty-four inches in height, was admitted to the hospital on November 17, 1938, in an unconscious and comatose condition. Barbital intoxication was suspected and it was estimated that twelve hours had elapsed since the taking of sixty grains of phenobarbital (luminal) obtained from a local drug store.

The patient's color was good, respirations slow and shallow, and she was comatose. Her temperature was 99.2 F., pulse rate 74, respiratory rate 16, and the blood pressure 92 systolic, 64 diastolic. The pupils were miotic (3 mm.), equal, regular, and did not react to light. The eyes were fixed in the midline, the corneal and conjunctival reflexes weak and sluggish. Her mucous membranes were moist and slightly cyanotic. The neck muscles were flaccid and all deep tendon reflexes were greatly reduced. The Babinski reflex was bilaterally negative. The admission diagnosis was: Overdose of hypnotic drug, probably barbital.

Course.—Gastric lavage was performed at once and only a small amount of fluid was found in the stomach. The bladder was emptied by catheterization and the urine found normal. The hemoglobin was 86 per cent; R.B.C. 4,620,000; W.B.C. 18,400. Five hundred c.c. of 10 per cent glucose in normal saline was given intravenously. The patient's temperature rose to 104.6 F.; pulse to 120; respirations to 32 per minute. Caffeine sodium benzoate (gr. 7½) was given subcutaneously and repeated with little apparent effect. The intravenous administration of picrotoxin was begun nine hours after admission, beginning with 1 mg. and repeating in increasing doses every twenty minutes until 6 mg. were given. Two to four hours were then allowed to elapse between doses, which were then increased to 9 mg. and then to 12 mg., depending on the blood pressure reading and the character of the pulse and respirations. During the first twenty-four hours of picrotoxin administration the patient received 111 mg. of picrotoxin intravenously and in the next twelve hours 36 mg. of picrotoxin by the same route, thus receiving a total of 147 mg. of picrotoxin in the thirty-six hour period. At the end of this time she developed a return of the deep reflexes, her temperature and pulse declined, and respirations became stabilized and deeper. Cyanosis disappeared and did not return. Feeding by duodenal tube was carried on for twelve hours, when oral feeding was possible. Strychnine gr. 1/20 was given subcutaneously three times daily after return of consciousness for its tonic and supportive effect. Recovery was considered well under way forty-eight hours after the institution of the picrotoxin administration. Strength and function of the upper extremities, however, returned late and weakness of these members persisted for seventy-two hours. The patient was released from the hospital on the fifth day after admission and was oriented, mentally clear, her temperature 99.4 F., pulse rate 90 per minute, respiratory rate 22 per minute, blood pressure 120 systolic and 66 diastolic.

The patient admitted having taken forty tablets of 1.5 gr. phenobarbital (luminal) or a total of sixty grains. It was observed during the administration of the picrotoxin that giving the drug intravenously at the rate of 1 mg. per minute did not produce any apparent untoward effects and that when the dosage reached 6 to 12 mg. certain signs of clinical improvement became apparent. This was evidenced by: (1) a rise of systolic and diastolic blood pressure; (2) a perceptible slowing of the pulse rate; (3) a deepening and slowing of the respirations; (4) a decrease of the cyanosis; and (5) a return of voluntary muscular movements. The return of consciousness occurred after the administration of a total of 147 mg. of picrotoxin in divided doses over a period of thirty-six hours.

Comment.—From the publications of Tatum et al[4,5] it was estimated that 1 mg. of picrotoxin is antidotal for 30 to 40 mg. of a barbital derivative. Upon the basis that 1 mg. of picrotoxin is antidotal for 30 mg. of phenobarbital, we have calculated that the 147 mg. of picrotoxin given this patient was sufficient to counteract 4,410 mg. of phenobarbital.

As this patient took 3,900 mg. (60 grains) of phenobarbital she received sufficient picrotoxin according to this method of calculation.

HISTORY OF MEDICINE IN RAMSEY COUNTY

BY J. M. ARMSTRONG, M.D.

(Continued from April issue)

1869

Though not pertinent to a history of medicine in Saint Paul, it may be noted that the Minnesota State Eclectic Medical Society was incorporated on May 26. E. M. Morehouse, M.D., was chosen President; Dr. S. M. Morrison, vice president; N. L. Culver, recording secretary; Dr. L. F. Case, corresponding secretary; and Dr. Charles Lee, treasurer. The censors were A. F. Elliott, M.D., J. W. B. Wellcomb, M.D., E. M. Morehouse, M.D. Some were doctors, some M.D.s, and some apparently were neither. It would be interesting to secure further knowledge of this organization. On November 14, the Southern Minnesota Eclectic Medical Society was incorporated. It was a larger organization than the former, and most of the men mentioned above belonged to it.

The usual number of itinerant physicians were in evidence this year. The city was growing, and apparently the field appeared promising to them. Several additional reputable physicians settled in Saint Paul, the first being Dr. T. B. De Grosbois. He formed a partnership with Dr. Guernon, but that association lasted only a few months, and he remained but a short time. He was a graduate of McGill University. Next came Dr. Charles H. Boardman, son of the Rev. Henry A. Boardman, pastor of one of the Presbyterian churches. Dr. Boardman became a prominent member of the Ramsey County Society in later years. Dr. E. Lemire, who stated that he was a graduate of Victoria University at Montreal, late editor of the *Gazette Medicale* and late secretary of the Medico-Chirurgical Society of Montreal, came to enter practice in September. Apparently the outlook was not favorable for he left after two months. As a matter of fact, the French element in our population, which was quite large previous to 1860, had now dwindled to a small minority and most of them were in very moderate circumstances. It is doubtful whether there was more than a living for one man to be made from a clientele composed largely of persons of French Canadian extraction. In November, Dr. William Ray, who had left Chaska in 1868 for Missouri and had practiced also in Iowa, returned to Saint Paul. A Dr. William Banks came with him. In August, Dr. Guy D. Daly (or Daley), who had come the year before, was elected county physician, but he resigned in December, going to Duluth. A retired physician from Missouri named William Baldwin also came to Saint Paul this year for his health. He did a little practice and remained till the time of his death in 1886.

Among the advertising physicians who came to Saint Paul this year was one Robert Hunter, who hailed from New York. He was a most persistent advertiser and used a column at least once a week, printing lectures, recommendations, et cetera. He brought with him "Dr. Rudolph Schiffmann, late of the St. Louis City Hospital, who will also act as interpreter for such German patients as do not speak English." Doctor Schiffmann remained many years. He made a fortune selling a cure for asthma. A Dr. Hunter applied for membership in the Ramsey County Medical Society in 1870, but he was rejected unless he ceased his "objectionable practice." Probably this was Dr. Robert Hunter. Late in the year a Dr. J. M. McKelvey came to Saint Paul, but remained only a short time.

The income tax returnes of Saint Paul physicians for the year ending May, 1869, are as follows. The figures include $1,000 exempt:

A. G. Brisbine	$1,094	D. W. Hand	$1,138
S. D. Flagg	2,648	John Steele	1,722
J. H. Murphy	1,500	J. H. Stewart	4,685
Russel Post	4,559	A. Wharton	1,250
T. C. Schell	1,331	Samuel Willey	1,707
F. R. Smith	1,671		

In January, 1869, Col. D. A. Robertson began the publication of a magazine called *The Minnesota Monthly*. Thirteen numbers were published. It was largely devoted to agriculture. Every number, however, contained articles on household medicine or hygiene, most of them by Brewer Mattocks. In one of them Mattocks referred to Drs. Hunter and Duval as quacks and stated that the latter was in jail awaiting trial for the murder of his wife. In the number published in July, 1869, the following announcement was made:

> Advertisements of quack medicines, gift enterprises, confidence games, clandestine obscenity and vice, and swindling nursery men and tree peddlers, humbug seeds, etc., etc., will be rigidly excluded.

There was considerable smallpox in Saint Paul during the first half of the year, about 125 cases being reported to the health office. In December the papers recorded that Dr. Hand performed Donder's operation of iridectomy for glaucoma, apparently the first time this operation had been performed in the city. There was a Dr. Somers in Saint Paul at this time and a Dr. F. Kerston. The latter was caught robbing George Presley's saloon. His office was upstairs.

Two deaths of physicians are recorded, that of John V. Wren, aged thirty-five, on December 11 at Magnolia, Mississippi; and B. L. Sellers at Wyalusing, Wisconsin, where he had resided for about two years. Both formerly lived in Saint Paul. Dr. Thomas E. Massey, who had resided in the city from 1857 to 1863, moved to Louisville, Kentucky. The following paragraph appeared in the papers on September 28:

> Dr. Thomas J. Vaiden, who once owned ten thousand acres of land in Wisconsin and Minnesota and mortgaged nearly all to go into the milk business and never sold a pint of milk, is practicing his profession at Mt. Zion, Tenn. He is about publishing a 600-page book on his favorite subject of a Pure Republic vs. Imperialism, etc., a la "America Vindicated."

This was the Dr. Vaiden who came to Saint Paul in 1855 and left about 1866. Vaiden was a Virginian by birth and graduated from the University of Pennsylvania in 1831.

The narrative has now been carried to the year 1870. There seems to be no necessity of making a summary of the decade from 1860, but a few words perhaps may be said of the contributions to medical literature by Saint Paul physicians during these years. Only a few references, other than those already mentioned, can be found.

Dr. D. W. Hand, aside from his army reports, contributed an article on cholera, as he experienced it among the troops in 1865. Dr. Alfred Wharton reported a case of "Puerperal Convulsions Treated with Chloroform," in the *Buffalo Medical and Surgical Journal* (Vol. I, No. 7, p. 213, February, 1862). Dr. Brewer Mattocks was author of an article on "The Effect of Climate upon the Lungs, with Special Reference to Minnesota" in the *Medical Record* for May 15, 1869. Dr. Samuel Willey contributed two articles: "Obstetrical Cases," in the *Cincinnati Lancet and Observer* (Vol. IV, No. 2, December, 1861), and "Dachylius Aculeatus" in the same journal (Vol. VI, N. S., p. 19, June, 1863). This last is an important communication as it is the first report of the finding of this parasite in the United States, and but one other case of infection has been reported in this country since. A number of articles written by physicians who later came to Saint Paul to reside may be found, but they are not included because these men were not residents at this time.

It seems worthwhile also to include here a bibliography of Thomas J. Vaiden, because listing his work gives us information as to his various places of residence, and many of them are not listed in the Surgeon General's Catalogue.

A review of medical activities during the sixties should also include a further mention of the Saint Paul Academy of Medicine and Surgery, which was organized March 1, 1860, and incorporated June 10, 1861. This was the first local medical organization to be established in the county. The officers and members for 1860 were:

President—Thomas R. Potts
Vice President—A. G. Brisbine
Treasurer—John Steele
Secretary—Alfred Wharton
Members—D. W. Hand, Samuel Willey, William H. Morton, F. Rieger, and J. H. Stewart; Honorary Members, Paul B. Goddard, Philadelphia; Joseph Leidy, Philadelphia; John Watson, New York; John L. Atlee, Lancaster; George McCook, Pittsburgh; Erastus Cushing, Cleveland; and John H. Murphy, St. Anthony.

On May 7, 1861, an eight-page pamphlet containing the constitution and by-laws of the Academy was published. This gives the officers for that year: A. G. Brisbine, president; Samuel Willey, vice president; D. W. Hand, librarian; the secretary and treasurer were the same as in 1860. The constitution states that "No person shall be admitted to the fellowship of this Academy . . . until he exhibits . . . satisfactory evidence of his being a graduate of some respectable medical school, recognized by the National Medical Association." The initiation fee was twenty dollars. In addition to monthly gatherings, an annual meeting was required which should take place on the first Tuesday in May of each and every year. Added to the pamphlet is the following note:

> "It affords the Secretary much pleasure to state, that at the termination of the first year of the existence of the Academy of Medicine and Surgery, it is in a most flourishing condition, and its permanent success established beyond the remotest doubt. Although numbering but nine members, and during a period of great monetary depression, the Academy is in

the possession of two spacious rooms, suitably furnished and well lighted with gas; has procured at no little expense, a superior microscope, an analytical chemical apparatus, and an electrical machine; for the skillful selection of all which the Institution acknowledges its indebtedness to the kindness of Dr. Paul Beck Goddard of Philadelphia.

"A medical library has been commenced, which bids fair to attain a very respectable size through the contributions of physicians and by purchase.

"The Treasurer reports:

Cash received during the fiscal year	$620.72
Cash expended during the fiscal year	462.93
Balance on hand at end of year	362.07

"It may be mentioned that the Academy early adopted the Code of Ethics of the National Medical Association.

"On behalf of the Academy, the undersigned would most cordially invite physicians from abroad, upon visiting Saint Paul, to make themselves known to the members thereof who will show them every attention in their power.

Alfred Wharton, M.D., *Secretary*

"Saint Paul, Minn., May 7, 1861."

The Academy obtained the positions of city and county physician for its president, and the members took turns in filling those positions, the emoluments of these offices being turned over to the Academy. A respectable income was thus assumed, during the earlier years at least.

Had this organization been able to survive the vicissitudes of the Civil War, no doubt it would have been strong and powerful. The story of its demise will be found in the narrative for the year 1866. Apparently, there was no change in its officers after 1861. It was necessary that five members be present to constitute a quorum, and it is doubtful whether during the war years a quorum could be obtained. The rooms of the Academy were in French's Block on Third Street. French's Block was a three-story stone building on the north side about where the driveway to the Public Library now is. In 1860, George Benz' saloon occupied the ground floor. As far as is known, no new members were ever admitted to the Academy. There seems reason to believe that the Academy contemplated the erection of a building, for in 1864 a payment was made on a lot on Third Street. We may also regard the Academy as giving some instruction in medicine, as medical students were allowed the use of their library and laboratory under their preceptors. The Academy also fostered Dr. D. B. Reed's lectures on chemistry during his stay here in 1861 and 1862.

Medicine in Saint Paul since 1870

The collection of data relative to the history of medicine in Ramsey County previous to 1870 necessitated considerable research, as there was no local medical literature in our state except the reports of the State Insane Asylum.

In 1870, the publication of the transactions of our State Medical Society was begun and the publication of our first medical journal, *The Northwestern Medical and Surgical Journal,* by Dr. Alexander J. Stone of Saint Paul. The minutes of our Ramsey County Medical Society are also preserved. These sources of information, together with the files of medical journals established at a later date, the minutes of other local and state societies make the gathering of material for medical history from this time on a comparatively easy task. The writer feels the better plan of procedure from this time is to give a brief outline sketch of medicine in Saint Paul, and if a more detailed history is desired some other more gifted person should take up the task. For this reason no biographic sketches will be included, and men prominent in the Ramsey County Medical Society will be mentioned only by name. Biographic material may readily be found. The writer also will confine himself largely to the history of the Ramsey County

Medical Society, since all physicians of prominence were members of it. It is true that there was a local and a twin city homeopathic medical society, but the followers of that cult never occupied positions of any prominence in medicine, and the more progressive among them were glad of the opportunity to be rated as physicians rather than homeopathic physicians. Before taking up the Ramsey County Medical Society a few incidents of general interest, not directly concerned with that Society, will be mentioned.

In 1870, Dr. Alexander J. Stone began the publication of the *Northwestern Medical and Surgical Journal.* Four volumes of this monthly journal were published. In 1872, the journal passed from his possession to Dr. Harry C. Hand, of Saint Paul and Dr. H. H. Kimball, of Minneapolis. Publication ceased in 1874. In 1881, Dr. Jay Owens founded the *Northwestern Lancet,* a bi-monthly publication, which later passed into the hands of Doctor Stone. After some years, it was sold and finally taken to Minneapolis. It has had a continuous and prosperous career since its beginning. In 1870, Dr. Stone founded the Saint Paul School for Medical Instruction. This school was designed to furnish more adequate and varied preparatory medical instruction than the preceptor system then in vogue. No degrees were conferred. The first faculty and officers of the school were:

Officers

President—Samuel D. Flagg
Treasurer—Charles E. Smith
Secretary—Alex. J. Stone

Board of Instructors

D. W. Hand—Surgery
Samuel D. Flagg—Materia Medica, Therapeutics and Diseases of Children
William Richeson—Anatomy and Chemistry
Brewer Mattocks—Physiology, Hygiene and Medical Jurisprudence
Charles E. Smith—Principles and Practice of Medicine
Alex. J. Stone—Obstetrics and Diseases of Women

In 1871, H. C. Hand taught pathology and J. B. Phillips, chemistry. In 1879, this school became the Saint Paul Medical College which was at one time affiliated with Hamline University. Classes were graduated and degrees conferred. In 1888, this school and the Minnesota College Hospital of Minneapolis gave up their charters when the Medical Faculty of the University of Minnesota became a teaching body. The history of medical instruction in Minnesota will be taken up in another portion of this book.

An event of considerable importance to the medical profession took place in Saint Paul in 1874. The Legislature of 1874 passed an abortion law, largely at the instance of the State Medical Society. Unfortunately, the law provided that an antemortem statement made under the belief of impending death was absolute proof of commission of abortion. The first fruit of this law was the conviction on June 9 of Dr. Jay Owens, who it was alleged, induced a pregnant female to take a medicine known as "Clark's Female Periodical Pills," and abortion followed. Owens was not allowed to introduce any testimony whatever, and was sent to the state prison. In November, Cushman K. Davis, who was Owen's attorney, was elected Governor and his first official act when he took office the following spring was to pardon Owens. The Legislature of 1875 then amended the law so that "no conviction shall be had upon the uncorroborated evidence of the woman." The first law made conviction easy, the modification made it difficult. In most states, no special rule of evidence for cases where abortion is charged exists, but the ordinary rule of evidence prevails. At the May, 1892, meeting of the Ramsey County Medical Society, the subject of abortion was discussed and resolutions were passed to bring this matter before the State Medical Association at the meeting of that year, and to have the Association recommend to the Legislature the repeal of the law of special rule of evidence. The failure of the State Association to take action was probably due to the fact that many of the members felt that there was some personal animosity back of the attempt to change the law. At the time of his conviction, Dr. Jay Owens was associated with Dr. Alexander J. Stone. Doctor Owens, after his release from prison, continued to practice medicine in Saint Paul, and in 1886 was elected president of the Ramsey County Medical Society. He died on April 17, 1890.

About 1890, Dr. Walter Reed, U. S. A., was stationed in Saint Paul as surgeon of the department of the Dakotas. He and Dr. Louis B. Wilson, now of the Mayo Foundation and then a teacher in the Saint Paul High School, had a bacteriologic laboratory in the school. Doctor Wilson learned bacteriologic technic from Doctor Reed.

Regarding the various hospitals in Saint Paul, only St. Joseph's and St. Luke's existed prior to 1870. The history of their establishment has already been noted. St. Joseph's Hospital has occupied its present site since the beginning. St. Luke's Hospital was incorporated in 1855 and re-incorporated in 1866 under the name of the Christ Church Orphans Home and Hospital. It was then located at Park Place. In 1873, it was moved to the north side of West Fourth Street, west of St. Peter Street, and in the spring of 1874 a large house on the north side of Eighth Street, between Minnesota and Robert streets, was purchased from Mrs. Mary A. Robinson. The present site was occupied in 1892. Mrs. Mary A. Bradbury, who was matron of St. Luke's from 1880 to 1895, died in Los Angeles, California, on August 6, 1932, aged ninety-two years.

The Saint Paul Homeopathic Hospital was organized and located at 800 Agate Street in 1887. It had a short life. The Saint Paul Hospital was first known as Luther Hospital, and was founded by Dr. Edouard Boeckmann. This hospital has now passed out of existence.

The history of the other hospitals in Saint Paul may be found in Fifield's *American and Canadian Hospitals.* Various small and private hospitals have existed from time to time, but were and are of no importance.

(To be continued in June issue)

President's Letter

THE Minnesota State Legislature has adjourned. As individuals we may have been interested in many actions that came under consideration. As a group of doctors we were interested only in problems that involved the health of the people.

One reason why Minnesota is right at the top of all states in the Union in health is our past and present Legislative Committees, which have given us in more recent years the Basic Science Law and the Medical Practice Act, and which have consistently advocated beneficial health measures.

We have had many splendid men serving on our Legislative Committees throughout the history of the organization. John Armstrong's Historical Committee will testify to that. From the standpoint of practical achievement, however, a more positive era of health legislation began in recent years. Frank Savage served as chairman of the Legislative Committee for a period of time, also J. T. Christison and then W. L. Burnap, an unusually active president, secured the services of Herman Johnson. With Dr. Johnson were C. B. Wright, J. M. Hayes, S. H. Boyer, Charles Bolsta, F. J. Plondke, G. I. Badeaux, E. A. Eberlin. Space will not permit naming the entire list of faithful committee members through the terms of chairmanship of Drs. Savage, Christison, Johnson, and Sogge.

L. L. Sogge, our present chairman, had his training under Dr. Johnson and was with him from the start. The committee under his leadership has carried on as ably as if Dr. Johnson were living. Dr. Johnson, himself, always gave great credit for the success of the committee's work to Mr. F. Manley Brist, our legal adviser. In this he has been most strongly joined by Dr. Sogge and by all who know of Mr. Brist's fine work for the medical profession of Minnesota.

On May 31 the State Medical Convention will open with an excellent scientific program, a valuable public health exhibit, an unusual program of economics and a surprise entertainment by the Hennepin County Medical Society. Every member should arrange to attend this meeting.

George Earl, M.D., *President,*
Minnesota State Medical Association.

ORTHOSTATIC HYPOTENSION: DIFFERENTIAL DIAGNOSIS AND TREATMENT

MAN is enabled to assume the upright position because he is endowed with a delicate mechanism for adjusting his blood pressure to offset the hydrostatic effect of change in posture. This function of circulatory homeostasis is mainly a protective mechanism intended to prevent deprivation of oxygen of the central nervous system. The circulatory correction is accomplished through vasoconstriction and cardiac acceleration.

Orthostatic hypotension is a clinical syndrome in which the usual compensatory mechanism does not function efficiently; consequently, with change to the upright position there is a marked decrease in systolic and diastolic blood pressure, resulting in cerebral anoxemia. The syndrome of orthostatic hypotension was first described clearly by Bradbury and Eggleston in 1925. They used the term "postural hypotension." However, the term "orthostatic hypotension" as suggested by Laubry and Doumer, seems preferable since it indicates the bodily position in which the hypotension occurs. Since 1925, about forty cases of the condition have been reported in the literature.

The exact nature of the failure of vasomotor control in orthostatic hypotension is as yet unknown. Because of the associated symptoms indicating dysfunction of the sympathetic nervous system (particularly hypohidrosis or anhidrosis and failure of normal cardiac acceleration), it is thought that the fault is in the sympathetic nervous system. The characteristic features of orthostatic hypotension are (1) a marked decrease in systolic and diastolic blood pressure on assuming the erect position, resulting in weakness or syncope; (2) localized or generalized hypohidrosis or anhidrosis; (3) failure of the normal compensatory increase in pulse rate on assuming the upright position; (4) increased distress of the patient during hot weather; and (5) secretion of larger amounts of urine in the recumbent than in the upright position.

The differential diagnosis of this condition involves separating it from other types of syncope, particularly simple syncope, syncope referable to sensitivity of the carotid sinus, syncope associated with hypersensitivity to cold, heart block, hypoglycemic reactions, and seizures of petit or grand mal. The presence of a postural hypotension should be suspected if the patient complains of weakness or syncope only after change to the upright position or after standing for a short time. The differential diagnosis is simplified by taking the patient's blood pressure in the recumbent and standing positions and demonstrating the presence or absence of a marked orthostatic decrease in blood pressure. The presence of hypohidrosis or anhidrosis and the failure of cardiac acceleration will differentiate orthostatic hypotension from simple syncope and the syncope which follows prolonged rest in bed, in which conditions there also may be an orthostatic decrease in blood pressure. The syncope caused by hypersensitivity to cold is accompanied by a decrease in blood pressure which is not directly related to posture. The history or demonstration of urticarial swelling of the skin when the patient is exposed to cold will readily differentiate the syncope of hypersensitivity to cold from the syncope of orthostatic hypotension.

In the syncope of hypoglycemic reactions, of sensitivity of the carotid sinus, of heart block, or of petit mal seizures, the postural features of the syncope will not be prominent and the characteristic signs of these conditions, i.e., low fasting blood sugar, a hypersensitive carotid sinus, and electrocardiographic changes or electroencephalographic changes, can be demonstrated.

The treatment of orthostatic hypotension is directed toward the maintenance of the blood pressure above the level which produces symptoms. Those drugs which produce vasoconstriction have been the ones most commonly used. Among those reported to have been used with success are ephedrine, benzedrine, paredrine[3,4] (beta-parahydroxyphenylisopropylamine), ergotamine tartrate, neosynephrine hydrochloride[5] (levo-metahydroxy-phenyl-ethanol-methylamine hydrochloride) and pitressin (the pressor principle of the posterior lobe of the hypophysis).

It is of interest that none of the drugs used for the treatment of orthostatic hypotension are very effective in preventing the orthostatic decrease in blood pressure. They alleviate the symptoms by elevating the general blood pressure, so that when the orthostatic decrease does occur, the lowest pressure reached is still above the point where weakness or syncope would be produced. In this respect, the situation is the reverse of that obtaining in some cases of essential hypertension, in which the administration of certain vasodilating drugs will maintain the blood pressure at a lower level, but will not prevent the same range of reaction of the blood pressure to stimulation. Ephedrine has been the drug usually chosen for the treatment of orthostatic hypotension. However, paredrine hydrobromide and neosynephrin hydrochloride are reported to produce equally as good results as ephedrine without the undesirable accessory reactions caused by ephedrine. The undesirable accessory effects of ephedrine and benzedrine are nervousness and insomnia. The patient having orthostatic hypotension usually can tolerate larger doses of ephedrine than can other persons, and relatively large amounts of this drug may be administered without producing unpleasant accessory effects. The best drug to use and the amount of it required are individual questions; the treatment must be adjusted to the patient. Some of these drugs may stimulate sweating sufficiently. If the anhidrosis is especially annoying, pilocarpine hydrochloride may be administered by mouth.

THE BARBITURATES AND LEGISLATION

THE last Minnesota State Legislature passed a law, similar to those already passed by some sixteen other state legislatures, limiting the sale of barbiturates to the public on prescription only. As far as the medical profession is concerned, the usual rules for the writing of a prescription apply; refills are not allowed without written or direct verbal authority from the prescriber. Physicians may be thankful that the inconvenience of writing refill prescriptions has been eliminated by legislation. This should make full coöperation on the part of the profession assured.

Although most physicians have encountered instances of the abuse of barbiturates, the article by Hambourger* must have been a revelation to many. It seems that at the meeting of the House of Delegates of the A.M.A. in June, 1937, a resolution was introduced on the evils resulting from promiscuous use of barbituric acid and derivative drugs. The resolution included the statement that "The evils of these drugs include habit formations, toxic cumulative action, their substitution for alcoholic beverages for drunken episodes, their use for successful, as well as unsuccessful, suicidal attempts, their improper use being a recognized causative factor in many motor accidents and their improper use being a recognized etiological factor in some criminal assaults. . . ." The report by Hambourger was limited to the phase of the use of barbiturates for suicidal intent and was published for the Council on Pharmacy. Some of the author's disclosures are startling and emphasize the need for legislation.

---

*Hambourger, W. E.: A study of the promiscuous use of the barbiturates. Jour. A.M.A., 112:1340, (April 8) 1939.

According to this author, more than 1,200,000,000 grains of barbiturates were sold in the United States in the year 1936. This, because of high United States duty, practically represents consumption in this country. What percentages are sold by druggists over the counter, dispensed by prescription, used for psychotics or for basal anesthesia, is unknown. At any rate, the total amount is much too much. United States Census Bureau figures show that in the five-year period, 1932 to 1936, inclusive, there were 634 suicides in the United States attributed to barbiturates—4.2 per cent of all suicides from poison. In 1936, 171 suicides were due to the barbiturates; 165 more classified as accidental deaths due to the barbiturates. It is, therefore, conservative to estimate some 300 suicides during 1936 from this cause. The number has probably increased since 1936.

The possession of large quantities of barbiturates is dangerous and should be classed with the possession of firearms. Either one being on hand is too convenient to use with suicidal intent during emotional upsets. There are probably as many unsuccessful as successful attempts at suicide by this means. Fully as serious a phase of the abuse of the barbiturates is the mental derangement reported at times from their habitual use. It would be instructive to know how many automobile accidents or criminal assaults are attributable to their use.

The medical profession has doubtless been to some extent responsible for the present vogue in sedation. Much of the need for sedatives could be avoided by a sensible restriction or elimination of stimulants such as coffee and nicotine. A realization of the enormous amount of barbiturates consumed should assure the coöperation of the profession in an attempt to reduce the use of these valuable drugs by careful prescribing.

LEGISLATION REGARDING BARBITAL

There is published herewith the complete text of the law enacted by the 1939 Minnesota Legislature on the subject of barbital, the derivatives of barbituric acid, and preparations containing such substances. This law was sponsored in the Senate by Senator Wahlstrand of Willmar and Senator Oliver* of Graceville. In the House of Representatives it was introduced by Representatives Paige of Minneapolis, Eklund* of Duluth and the late Dr. Lowe of Pipestone.

Much credit is due Senator Wahlstrand for the passage of this law. His interest was due to the abuses attending the unrestricted sale, in drug stores, to children and barbiturate addicts of these various preparations. Senator Wahlstrand stated he had no desire to impose restrictions on the ethical practitioner of medicine and publicly commended the Minnesota State Medical Association for their assistance in drafting and passing the law. The law requires no special permits on the part of physicians nor does it call for any fee. It simply states that a physician must act "in good faith" in the prescribing, administering and dispensing of barbital. Drug stores, however, cannot sell barbital, as defined in the act, except on the prescription of a physician, dentist or veterinarian, as the case may be.

Every member of the Minnesota State Medical Association is urged to read this law, and particularly the provisions in reference to writing prescriptions. Remember! they cannot be refilled without your *consent*. The authors of this law are your friends—the measure is a public health act—do your very best to comply with it and to help in its enforcement.

Committee on Public Policy,
Minnesota State Medical Association,
L. L. Sogge, M.D., *Chairman*.

An Act

Regulating the Sale, Gift, Order, Exchange, Distribution and Possession of Barbital, Barbituric Acid, Its Compounds and Derivatives, and Providing Penalties for Its Violation.

Be It Enacted By the Legislature of the State of Minnesota:

Section 1. It shall be unlawful for any person, firm or corporation to have in his, or its, possession, or to sell, give away, barter, exchange or distribute barbital, except on a written prescription of a doctor of medicine, doctor of dental surgery, or doctor of veterinary medicine, lawfully practicing his profession in this state.

Section 2. For the purposes of this Act, the word "barbital" means: barbital and any derivative thereof; diethylbarbituric acid; any alkyl, aryl, metallic or halogenated derivative of barbituric acid; veronal (barbitone); proponal; ipral; dial; neonal (soneryl); sandoptal; amytal; phenobarbital (luminal); phandorn; noctal; allonal (which contains allylisopropyl-barbituric acid in combination with amidopyrine); medinal; any preparation, mixture or other substance containing any of the foregoing substances.

Section 3. No person other than a licensed pharmacist, shall sell barbital, and then, only as provided in this act.

Section 4. For the purposes of this act, a prescription for barbital is void unless (1) it is written in ink and contains the name and address of the person for whose use it is intended; (2) it states the amount of barbital to be compounded or dispensed, with directions for its use; (3) it contains the signature and address of the prescriber, and a designation of the branch of the healing art pursued by the prescriber, and (4) it shows the date when signed by the prescriber. Every licensed pharmacist who compounds any such prescription, shall at that time, mark it in ink so as to show that it has been compounded, and the date thereof, and he shall retain such prescription in a separate file for a period of not less than two years, open to inspection by any officer of the state, county or municipal government, whose duty it is to aid and assist with the enforecment of this act. No such prescription shall be refilled, except with the written or verbal consent of the prescriber, provided that the date of such consent must be recorded, in ink or indelible pencil, upon the original prescription by the pharmacist who refills the said prescription together with the name of said pharmacist, and provided further, that in event of verbal consent it must be direct from the prescriber to the said pharmacist. Every such pharmacist shall distinctly label the container with the directions contained in the prescription for the use thereof, and the following warning: *"Use Only As Directed."*

---

*Physicians.

Section 5. (1) A licensed doctor of medicine, or a licensed doctor of dentistry, in good faith, and in the course of his professional practice only, may prescribe, administer, and dispense barbital, or he may cause the same to be administered by a nurse or interne under his direction and supervision.

(2) A licensed doctor of veterinary medicine, in good faith, and in the course of his professional practice only, and not for use by a human being may prescribe, administer, and dispense barbital, and he may cause the same to be administered by an assistant under his direction and supervision.

(3) Nothing in this act shall prohibit the sale to, nor the possession of, barbital, by wholesale drug concerns, registered pharmacies, licensed pharmacists, licensed doctors of medicine, licensed doctors of dentistry, licensed doctors of veterinary medicine, or any bona fide hospital or other bona fide institutions wherein sick and injured persons are cared for or treated, or bona fide hospitals wherein animals are treated.

Section 6. Any person, firm or corporation that violates any provision of this act shall be guilty of a gross misdemeanor, and upon conviction thereof, shall be punished by a fine of not to exceed $1,000 or imprisonment in the county jail for not to exceed one year or by both such fine and imprisonment.

Some of the preparations regulated under Section 4 of the Barbituric Law and which now must be dispensed only with a doctor's prescription written in ink are as follows:

Amytal Tablets
Amytal Elixir
Amytal Compound Capsules
Amytal C Acetylsalicylic Acid
Amytal & Ephedrine Capsules
Amytal & Theamin Capsules
Amytal Sodium Capsules
Amytal Sodium Suppositories
Amytal Sodium Ampoules
Epragen Capsules
Barbital Tablets
Allonal
Arlcaps
Alurate
Amidopyrine & Phenobarbital
Aminophyllin & Phenobarbital
Adalin Luminal
Amidoneonal
Kres-Lumin
Luminal Tabs.
Luminal Elixir
Luminal Sodium Tablets
Luminal Sodium Ampoules
Barbitone
Bellergal
Belladenal
Barbella
Calcidrine Syrup
Cibalgine
Dial
Evipal
Evicyl
Epharbital
Ephedraphen
Iocapral
Ipral Calcium
Ipral Sodium
Ipral Elixir
Ipral Aspirin
Ipralidon
Mebral
Medinal Tablets
Neonal Tablets
Neonal Compound
Neonal Elixir
Nembutal Capsules
Nembutal Elixir
Nembutal Suppositories
Nembutal & Aspirin
Ortal Capsules
Ortal Combinations
Peralga Tablets
Penobarbital
Pentabarbital Sodium Capsules
Theodiatal Capsules
Tedral Tablets
Thebital Tablets
Theominal Tablets
Veronal
Dialacetin
Lumalgin
Lumodrin
Nembutal & Ephedrine Capsules
Novasural
Ortal Sodium Capsules
Ortal Ampoules
Phanodorm Tablets
Phenobarbital Sodium
Pentabarbital Sodium Suppositories
Sedabarb
Sedaphen
Theobromine Compound Tablets
Ethobral Tablets
Veronal Sodium
Ephatal Capsules

SAL TRAG FOR ARTHRITIS

As an herb remedy for arthritis, called Sal Trag, is being offered to the local profession, the following information may be of interest:

In June, 1924, the Federal Trade Commission at Washington reported that Sal Trag and Nue-Ovo were practically the same product. Sal Trag is the name given this remedy of secret composition when offered to the profession, and Nue-Ovo is the name given when it is sold to the public. Sal Trag is probably more concentrated. In 1929, the Food and Drug Administration reported in a notice of judgment that Nue-Ovo was misbranded because it was being sold under false and fraudulent therapeutic claims. At that time, the federal chemists declared that the preparation was a brown watery solution of extracts of plant drugs, including a laxative drug, a bitter drug, resin, saponin and caffeine, colored with caramel and preserved with sodium benzoate.

There is at least one report of a severe inflammation of both eyes, with a residual visual defect in a woman who had taken Nue-Ovo for arthritis. It is dangerous and not good practice to prescribe drugs of unknown composition, or containing ingredients, the action of which is not known.

Oral Pollen Preparations

Early last year the Chicago Society of Allergy issued a note of warning in reference to the use of oral pollen preparations, not only because of the probable numerous disappointments which might occure following the use of oral pollen preparations but also because of the possible dangers inherent in any new and unproved method of treatment. In *The Journal,* March 25, 1939, appears a new communication from the Chicago Society of Allergy. The Society is to be commended for its stand against the exploitation of a product for oral administration in the treatment of hay fever which may be not only beneficial but a decided economic loss to the patient. The difficulty of regulating dosage because of the difference in rate of absorption from the gastrointestinal tract alone is a serious objection to this mode of therapy. It will require considerable evidence to show by passive transfer work that pollen is absorbed in the doses intended. The Council on Pharmacy and Chemistry of the American Medical Association has accepted no pollen preparation proposed for oral administration. *(J.A.M.A.,* March 25, 1939, p. 1159).

MEDICAL ECONOMICS

Edited by the Committee on Medical Economics
of the
Minnesota State Medical Association
W. F. Braasch, M.D., Chairman

HOW SHALL MEDICAL CARE BE IMPROVED?

NO ONE would deny, least of all physicians, that medical care of the people of our country can and should be improved, but there is vast divergence of opinion as to how that improvement can be brought about.

Representatives of one school of thought reiterate the unverified and unverifiable statement that a third of our population receives inadequate medical care. This viewpoint seems to imply that the percentage of the population which receives inadequate medical care is immeasurably greater than it was in times past. Anyone whose experience covers a period of three or four decades knows emphatically that this is not the case. The innumerable projects to which physicians have given their services, including dispensaries, sanitariums, hospitals for crippled children and programs for prevention of communicable diseases have resulted in much wider and more effective distribution of medical care than formerly was available. The conquest of communicable disease, the constantly falling death rate from tuberculosis and the increasing span of life attest the efficacy of these services and denote an achievement that exempts the medical profession from a charge of incompetency, to say the least.

The list of achievements is long. What would life be today without vaccination for smallpox, immunization against diphtheria, antidiphtheritic serums, insulin, liver extract for pernicious anemia, antipneumonococcus serums and, lately, sulfanilamide and sulfapyridine, to mention only a few agents and methods for control and cure of dreaded diseases?

Shrewd Gesture

It is a shrewd political gesture to proclaim the urgent need for wider distribution of medical agents and services. In like manner politicians have found it wise to declare for ham and eggs every Thursday or for the Townsend plan, to secure their election, without any great concern about a source of revenue to finance such schemes or indeed, one suspects, without any serious intent of supporting such harebrained proposals after their election. If one opposes the Government's plan to secure a wider distribution of medical care, though subscribing to the worthiness of the objective, one is labeled a reactionary and accused of lack of humane instincts.

The fundamental reason the medical profession is opposed to socialized medicine as proposed by the present administration is its instinctive surmise that it has a political motivation. Those who compose the public are asked to accept the Government's apparent solicitude for their health as a purely altruistic gesture in no way related to their vote in the coming election. They are asked to forget that in one more respect the Federal Government will reach down and regulate one of their most precious prerogatives, namely, their relation with their physicians. They are asked to believe that appointments of physicians to care for their health will be based solely on competency, rather than on the basis of political expediency. They are asked to forget that bureaucracy in medicine is no different than it is in any other field, devouring too large a measure of their funds designed to provide for their medical care.

Only the Husks

The same public is asked to believe that a physician in a more or less regimented system will have the same incentive to make medical discoveries, to advance his medical knowledge, or to treat each patient with the same degree of thoroughness as he would if the present competitive practice based on free choice of physician existed. In a system of medical care dominated by governmental regulation, the citizen is likely to wake up to find that he has sold his medical birthright for a mess of governmental pottage and to learn that he is receiving only the husks of medical care.

This is not to deny the need for adapting medical practice to changing medical needs. The medical profession is progressive and believes in the necessity of continual growth and adaptation. But it has a few fundamental beliefs as to the way those changes should be made. It believes that the change must be evolutionary and not revolutionary, if colossal mistakes are to be avoided. It does not believe that there is any substitute for local administrative responsibility for securing efficient medical services adapted to local needs. It believes that as a body it is better qualified than any other group of people to formulate plans for improvement of medical care in its own community, that it must have a vital part in the executive policies controlling any effective health program and, finally, that the freedom of a patient to select the physician of his choice is essential to any plan of governmental assistance in medical care and is an inalienable right of a patient in a free nation.

Profession Will Coöperate

I am sure that the medical profession will gladly coöperate with the Government in a program of better medical care that is based on these principles. Unless we have lost our faith in local self-government these principles are sound and are in keeping with the ideals on which our democracy is founded.

W. F. B.

EXPERIMENTS IN MEDICAL SERVICE

The leaven of reform is working in the ranks of medical organizations much as the New Deal politico-sociologists had hoped and planned. Propaganda has put across the grossly exaggerated claims of lack of medical care on public opinion and the politicians now are watching results. Believing that there is a popular demand for sickness insurance and in order to stop legislative demands, various state and local medical societies either have or are about to propose plans for sickness insurance. Spurred on by the apparent success of group hospital insurance, somewhat similar methods are being applied to medical care. Any plan which would permit of an equable distribution of the costs of illness among patients and which would not alter the present system of medical practice would seem worth striving for. With this purpose in view, voluntary methods of sickness insurance are being offered to the public in many sections of the country. This in spite of the warning issued by most economists that voluntary systems of health insurance are doomed to failure and invariably lead to compulsory insurance.

How are these plans working out? It is, of course, too early to make any definite observations but difficulties are already developing to plague the sponsors. For instance, the health service system of medicine adopted in one large city, which started out bravely over a year ago, offering health care at bargain rates, gives evidence of having serious difficulties. The unit system of reimbursement for medical services rendered which was originally evaluated at $1.00 is now reduced to about 18 cents. In other words, the overhead administrative costs have increased to such extent that the reduced net income leaves very little for the doctor. This is only one of many other unforeseen difficulties. The latest is that the drugless practitioners are insisting upon being added to the professional staff and, being a semi-public project, their demands have a good chance of being adopted.

Minnesota Is Fortunate

As Dr. C. B. Wright recently emphasized before members of our state medical society, no plan of unproven economic value which is being promoted for the purpose of preventing the legislative adoption of another plan is on a sound basis. There are too many factors which are bound to cause trouble in the plans which have been proposed so far.

We physicians in Minnesota are indeed fortunately situated. In the first place we have a well-trained profession, who are practicing good medicine to the satisfaction of the majority of the people. They have been most generous in giving medical care to the sub-economic groups and have made many sacrifices in these uncertain times. They believe that the present methods of distributing medical care will prove to be the best in the long run for all concerned. The great majority of the people of the state have not been greatly influenced by federal propaganda so far, because they mistrust governmental medicine.

Our Courageous Colleagues

Let us then continue to remain as observers of the very interesting spectacle of federal efforts to force sickness insurance on the public on one side and on the other side watch the courageous efforts of our colleagues in various parts of the country charting the unknown seas of medical distribution. Let us be open-minded, however, and if any sound improvement on our present system proves to be worthwhile, by all means consider it. Slow and well considered evolution in the delicately balanced institution of medical practice would seem to be a logical course. In the meantime, let us concentrate on improving our methods of practice by systematic efforts to enlarge our knowledge of medicine. This is the best answer to public dissatisfaction.

W. F. B.

NEW CHOICE OF VENDOR CLAUSE

Many legislative enactments of great interest to physicians marked the notable 1939 session just concluded.

Among them is the Barbital Law commented upon elsewhere in this issue of MINNESOTA MEDICINE. The Reorganization Law is also of special interest to physicians on two accounts. First, it puts the administration of all services involving medical care to relief clients and to recipients of social security aids in one department under one directing head. Thus the ground work is laid for elimination of long standing duplications, misunderstandings, over-lapping and gaps in services. Second, it maintains the former status of the State Board of Medical Examiners as an independent board, independently supported by fees of licensed physicians. The original provisions of the bill called for a tax on the funds of all boards and likewise gave the administrator power to consolidate and otherwise regulate them. Long experience with this board as it has functioned under Minnesota's model basic science legislation and medical practice act has shown the wisdom of maintaining it as a self-sustaining agency.

Law Clarified

Of immediate personal importance to every physician in the state is the new choice-of-vendor clause which was restated in the new relief law with a clarifying phrase which should end any further discussion as to its applicability to the services of the physician. As the law now reads the relief client is specifically guaranteed his choice-of-vendor for *services and supplies.*

The choice-of-vendor clause as written in the 1936 law ushered in a new era in the handling of medical relief in Minnesota. Whereas there had been free choice of physician for the indigent in a few counties before 1936, many other counties still retained the county physician system of care for the sick poor and his legal status was unquestioned.

Discussion: Complaints

With the new law and the subsequent interpretation of the Attorney General which definitely placed the physician as a vendor within the meaning of the law, the county poor physician became a thing of the past in all the counties that accepted state aid.

The question remained an issue, however, with county commissioners and welfare boards questioning the interpretation of the Attorney General in several quarters. Lively discussion of the merits of the free-choice-of-physician system have marked several county welfare board conferences of late and complaints have been voiced concerning the cost.

Trust Merited

The action of the legislature in clarifying and strengthening the choice-of-vendor clause, in the face of these discussions, constitutes a double reassurance to the physicians. It indicates first that the rights of the individual are still regarded as important rights by Minnesota legislators. It indicates, also, the trust which is reposed in the medical profession in Minnesota. This trust has been well justified, not only during the relief years but over all the years when the physician alone shouldered the burden of the sick poor in his locality with occasional and uncertain aid from the authorities.

It goes without saying that members of the Minnesota State Medical Association will cooperate heartily with county welfare boards to continue to merit that trust and to keep medical costs as low as possible in these difficult years of relief financing.

FOR A STUDY OF SEX CRIME

The bill providing for the apprehension of potential sex criminals was regarded by its sponsors and by both branches of the legislature as a preliminary step, only, in the control of the problem of sex crime.

The Minnesota State Medical Association and the Minnesota State Bar Association were named jointly by the House Judiciary Committee which recommended passage of the bill as "technically equipped to make invaluable recommendations towards the solution of this problem."

A resolution requesting that the State Bar Association and the State Medical Association appoint committees from each body to study the subject of psychopathic personalities and also that the committees so appointed transmit a report of their findings as well as their recommendations to the governor and to the House of Representatives at the beginning of the legislative session of 1941 was passed by the committee and subsequently transmitted to the secretary of the association.

These reports will be utilized to formulate further and additional legislation to cope adequately with this problem.

The request of the House Judiciary Committee will be presented to the Council of the Association at the annual meeting, May 31, June 1 and 2, in the Minneapolis Auditorium.

DIFFICULTY IN DULUTH

A new fee schedule with regulations and instructions has just been issued by the St. Louis County Welfare Board. After many years of close coöperation between physicians and welfare board in St. Louis County, this schedule has aroused a just resentment among those who have assisted in making St. Louis County the envy and admiration of many other localities in the state for the smoothness and efficiency of its system.

"It is the desire of the County Welfare Board," say the new instructions, "to maintain the contact of the private physician with his former patients who may now be county charges, but at the same time it expects the private physician to render dependable service and to *continually bear in mind the fact that it is the taxpayers' money that is being spent.*" Well, there are over a hundred physicians referred to in this community who are some of the taxpayers. They have been taking care of these people, who are now charges, down through the years, through good times and bad. Without a Welfare Board to watch over them and to tell them what it "expects" of them, physicians have rendered dependable service to these patients who are now, perhaps temporarily, receiving county aid. It sounds like a play of words to impress the public and also a bit dictatorial. Following the preamble quoted above, some of the absurdities of a fee schedule are listed such as "collarbone fracture, $7.50" and "clavicle fracture, $25.00; nose fracture, $12.50" and "nose broken, $37.50," all of which suggests that physicians, "expected to render dependable service," were not consulted in the formulation of the fee schedule.

A. N. C.

"AIM: TO SAVE LIVES"

The effectiveness of the 1939 Co-Ordinated Medical and Public Health Program is measured to some extent by the response and coöperation it has evoked from Minnesota newspapers.

No newspaper has shown more intelligent interest in medical news and in public health education in general than the *Minneapolis Journal*. The editorial printed below appeared on Monday, April 3. It is reprinted here as evidence both of the coöperative spirit of the *Journal* and of the effectiveness of this new program:

> ### Cancer Prevention
>
> Time is an all-important factor in the arresting of any serious disease, and in none is early treatment more important than in cancer. For this scourge creeps up stealthily, like a thief in the night, and its early symptoms seldom cause alarm.
>
> The State Medical Association is carrying on an educational campaign this month, to save lives from cancer. The disease caused 3,775 deaths in Minnesota last year, and was second only to ailments of the heart in fatalities. The job the medical men are undertaking is to make older persons conscious of the danger of cancer, so they will not hesitate to have diagnoses made whenever there is cause to suspect approach of the disease. Better still would be periodical check-ups. Physicians say that not more than 15 per cent of cancer cases are discovered in time for effective treatment. Given an earlier detection of cancer, fully half the deaths from this disease could be prevented.

The Women's Field Army Against Cancer, now conducting a membership drive, has the same purpose as that of the physicians. Both organizations are trying to overcome the foolish reluctance of so many persons to give the doctor a chance—to head off fatal illness by going to him in time. The efforts of these organizations deserve support and appreciation. Their aim is to save lives.

KNOW YOUR DRUGS

(Monthly Editorial Prepared by the Medical Advisory Committee)

From time to time your Medical Advisory Committee has brought to the attention of the members various conditions, arising in the treatment of patients, that are being used by these patients as reasons for bringing action in court against our membership. In the last months numerous cases have arisen from alleged malpractice in the use of the injection methods of treatment, the use of sclerosing injections in varicose veins, hemorrhoids, and hernias, the injection of serums without first finding out the reactions of the patient to such serums, the injections of the salts of arsenic and salicylates as well as other well known remedial agents.

Knowing this, it is well to remember that normal tissues can be harmed by these solutions and that some people are particularly allergic even to the smallest amount of some drugs.

It behooves the man making these injections and giving these treatments, therefore, not only to have a firm groundwork in the fundamentals of this method, but to be sure of the purity and accuracy as to dosage of the drug used, as well as the ability and financial standing of the manufacturer to back up any claims which they may make for the drug. Unscrupulous manufacturers are making extravagant claims which have no foundation in fact. You can well be made the unwilling victim of these claims.

In this day and age the best is still none too good. Know your drugs and know how and when to give them.

B. J. B.

CONFERENCE SPEAKERS

Speakers who are scheduled to participate in the Conference on Medical Problems which occupies the final day's sessions, Friday, June 2, of the 86th Annual Meeting at the Minneapolis Auditorium, are authorities in their fields. All are making definite contributions to the solution of medical and public health problems in America.

Gen. C. E. Waller of the United States Public Health Service is Surgeon-General Thomas Parran's right hand man in Washington and in the field. He is one of the key men in the program of the public health service.

Dr. F. W. Jackson of Winnipeg has been deputy minister of health of Manitoba (the minister, himself, is an elected official and a layman) for many years. He has watched the development of Canada's experiments with new technics of medical service and he has officially represented the medical profession in this development.

Mr. J. G. Crownhart, secretary of the Wisconsin State Medical Society, has made one of the most important contributions of our time to American knowledge of socialized and state medical systems in Europe. He is also leading his organization in a fight against the corporation income tax which may be of the utmost importance to every state medical association in the United States. The Wisconsin society won its initial legislative battle in a state skirmish for socialization of medicine in the Wisconsin legislature last year.

The Rt. Rev. Monsignor M. F. Griffin of Cleveland is Senior Trustee of the American Hospital Association and an active official in the Catholic Hospital Association, powerful defender of private and voluntary investment in our system of care for the sick.

Mr. J. A. A. Burnquist, attorney general of the State of Minnesota, is also a former governor of the state and exceptionally well qualified to talk on the history and character of Minnesota's legislation for care of the sick poor.

Dr. F. Stuart Chapin is chairman of the Department of Sociology of the University of Minnesota, director of the graduate school of social work and a nationally recognized authority on social needs and social problems, among which the problem of distribution of medical care has loomed large as a result of events of the last few years.

In addition to these guest speakers, Dr. W. A. O'Brien, the association radio speaker, and President George Earl, will be present to represent Minnesota physicians, with Dr. Frank Savage of Saint Paul, and Dr. W. F. Braasch of Rochester, as presiding officers.

The program is unique, the conference the only one of its sort to be held this year by any state medical association. Every physician in Minnesota should make it a special point to attend.

MINNESOTA STATE BOARD OF MEDICAL EXAMINERS

Mankato Physician Enters Plea of Guilty

Re: State of Minnesota vs. Arthur W. Eckstein, M.D.

On April 8, 1939, Arthur W. Eckstein, M.D., of Mankato, Minnesota, entered a plea of guilty to an information charging him with the crime of abortion committed on or about October 15, 1938, in the city of Mankato. Dr. Eckstein was also arraigned on a previous conviction (1934), and at the conclusion of which he was sentenced by the Honorable Harry A. Johnson, Judge of the District Court, to a term of not to exceed four years in a state penal institution. The Court was advised by legal counsel for the defendant that Dr. Eckstein's license to practice medicine had been revoked by the Minnesota State Board of Medical Examiners on December 16, 1938, for procuring, aiding and abetting a criminal abortion. Counsel also stated that Dr. Eckstein was employed by a wholesale pharmaceutical house of Milwaukee, Wisconsin, and that he was engaged in sales work for that concern in the eastern half of Iowa. Following a lengthy plea by Dr. Eckstein's lawyer, the Court suspended the sentence and placed Dr. Eckstein on probation in charge of the State Board of Parole. The Court warned Dr. Eckstein that in 1934 he had served a sentence in the State Prison for a similar offense, and that any violation of his probation, would result in his having to serve the entire sentence.

Dr. Eckstein was born at New Ulm, Minnesota, December 8, 1888. He graduated from the Medical School at Northwestern University in 1912. He was first licensed in Minnesota, by examination, in the same year, but had his license revoked in 1934, following his pleading guilty to a similar offense. Despite the fact that he was permitted, upon his release, to take the medical examination for a new license, and was subsequently granted a license, he again became involved with the law over the performing of a criminal abortion, resulting in the present criminal charge and the revocation of his license by the Medical Board on December 16, 1938.

OF GENERAL INTEREST

Dr. and Mrs. Daniel A. MacDonald left April 30 on a European trip. They will return July 1.

* * *

Dr. R. E. Cooper is the newly-elected school board member of the community at Sauk Center, Minnesota.

* * *

Dr. C. F. Wohlrabe, formerly of Minneapolis, has taken over the practice and hospital previously attended by Dr. M. H. Larson, at Nicollet, Minnesota.

* * *

Dr. S. D. Wolsztajn, who was previously associated with Dr. O. Daignault at Benson, has opened an office in Minneota for the practice of medicine.

* * *

Dr. A. F. Dworak is now practising medicine and surgery at Rosemount, Minnesota, where he opened offices in the Geraghty Building on Monday, April 17.

* * *

Dr. David Gaviser has recently associated himself with Dr. R. F. Werner, of International Falls. Dr. Gaviser was formerly on the staff of Minneapolis General Hospital.

* * *

Dr. Lynn Hammerstad, Windom, Minnesota, recently was appointed by federal authorities to serve as federal medical examiner of students registering for courses in aviation at the University of Minnesota.

* * *

Dr. Robert B. Tudor, of Minneapolis, joined Dr. J. F. Cumming of Morris, Minnesota, the first of April, in the practice of medicine. Dr. Tudor has come to Morris after serving interneships at several hospitals in the Twin Cities.

* * *

Motion pictures, through the courtesy of General Electric Company, were shown at the meeting of the Rice County Medical Association held April 5 in the Faribault Clinic Rooms. The movies portrayed the electro-cardiographic process.

* * *

Dr. P. J. Bursheim, who for some time past has been in the retail drug business at Atlantic, Iowa, has resumed his practice of medicine in the community of Exira, Iowa. Prior to his entering the drug business, Dr. Bursheim served the community of Lake Benton, Minnesota, as physician and surgeon.

* * *

Charles Bishop Will of Bertha, Minnesota, received his degree of Doctor of Medicine at the early spring commencement held recently at the University of Minnesota. For the past year, Dr. Will has been serving an interneship at Saint Luke's Hospital in Duluth. He will practice medicine at Ladysmith, Wisconsin.

* * *

Dr. M. G. Franta, Sauk Center, Minnesota, was appointed in March to take applications from young men who wish to enter one of the camps provided by the federal government for young men from the ages of 17 to 24 years. Dr. Franta's title in this capacity is chairman of the Seventh Corps Area, Citizens' Military Training Camps.

* * *

Dr. Gerald Taylor Evans, Assistant Professor of Physiological Chemistry, Yale University, has been appointed Associate Professor of Medicine and Director of Chemical and Metabolic Laboratories, University Hospital, University of Minnesota. Dr. Evans received his M.D. degree from McGill University in 1929 and his Ph.D. in Medicine from the University of Pennsylvania in 1936.

* * *

After more than forty-four years of service, Dr. G. E. Vaughan, of Winnebago, has made known his intention to retire from the practice of medicine. He has removed his offices from the Germain Building in Winnebago, to his residence, where he will care for those patients who especially wish him to attend them in their illness. He expects to have withdrawn entirely from active practice by next fall.

* * *

"Polypoid Disease of the Colon" is the title of Dr. R. F. Hedin's prize-winning essay which won for him the sum of $250.00, awarded by the Chicago Surgical Society for his report on original clinical investigative work. The paper will be presented before the Chicago Surgical Society on May 5. Dr. Hedin, who has been doing graduate work in Chicago, will return this summer to Red Wing to resume his practice.

* * *

The Saint Paul Surgical Society was host to prominent physicians from Chicago, Milwaukee, Duluth, Rochester, and Minneapolis, at its annual dinner on Thursday evening, April 13, in the Minnesota Club. Dr. Loyal Davis, professor of surgery at Northwestern University, Chicago, and well-known writer of medical treatises, was principal speaker of the occasion. Dr. W. C. Carroll is president of the Saint Paul Surgical Society.

* * *

Drs. George A. Earl and Everett K. Geer were principal speakers at the regular monthly meeting of the Washington County Medical Society held Tuesday evening, April 11, in the society's club rooms at Stillwater. Dr. Earl discussed in detail modern technics in the diagnosis and treatment of cancer of the gastrointestinal tract. Dr. Geer gave an illustrated lecture based on seventy-three x-ray plates of the chests of positive Mantoux reactors.

* * *

Professor August Krogh and his wife, Dr. Marie Krogh, of the University of Copenhagen, were guests of the Medical School of the University of Minnesota for ten days (March 25 to April 4). During their visit Professor Krogh presented lectures and seminars on the following subjects: "Osmotic and Ionic Regulation in Animals," "Circulatory Adjustment to Posture in Man," and "Comparative Physiology of Respiration." Dr. Marie Krogh presented a lecture on "Nutritional Problems in Denmark."

* * *

Dr. L. H. Rutledge of Detroit Lakes was named chief of staff at Saint Mary's Hospital there, when nine doctors of the county convened Tuesday, March 21, to hold a hospital staff organization meeting. Drs. O. O. Larsen and Arnold Larson were named vice president and secretary, respectively. Drs. J. E. Carman, A. E. Sprafka, H. W. Arndt, A. R. Ellingson, all of Detroit Lakes, G. G. Haight of Audubon, and C. W. Moberg of Lake Park, are also staff members of the hospital. Sister Monica superintends the institution.

* * *

The Itasca County Welfare board and hospital commissioners have made the following appointments for the ensuing year: Dr. M. J. McKenna, Grand Rapids, county surgeon; Drs. J. H. Bender, Bigfork; Dr. G. A. Miners, Deer River; Dr. G. M. Erskine, Grand Rapids; Dr. E. K. Rowles, Coleraine; Dr. J. C. Fueling, Bovey; Dr. E. T. Plowman, Marble; and Dr. E. H. Loofbourrow, Keewatin, as county physicians for their respective localities; Dr. C. E. Sisler, Grand Rapids, as house physician for the county home and infirmary. Appointed to act on the board of examiners for the University Hospital are Dr. M. J. McKenna and Dr. C. E. Sisler.

* * *

The fiftieth annual Founders' Day dinner of the Psi chapter of Alpha Kappa Kappa was held at the Kahler Hotel in Rochester, Minnesota, on Saturday, April 22. Drs. A. E. Brown, chairman, E. A. Addington, W. F. Braasch, M. W. Comfort, V. S. Counseller, E. J. Kepler, J. S. Lundy, H. W. Meyerding, L. W. Pollock, M. C. Piper, Waltman Walters, and H. W. Woltman were members of the committee in charge which arranged for the all-day program preceding the banquet. In the morning, clinics were held in various hospitals of the city. A noon luncheon followed at the Mayo Foundation House, with the initiation of thirteen new members of the chapter. Clinics were resumed in the afternoon. Undergraduate members of the fraternity from the University of Minnesota attended in a body. Many physicians from Saint Paul and Minneapolis drove to Rochester for the occasion. Attendance was estimated at approximately 125.

In Memoriam

Finley C. Spates

1855-1939

DR. FINLEY C. SPATES, a practicing physician of Saint Paul for fifty-two years, passed away February 27, 1939, at the age of eighty-three.

Dr. Spates was born near Red Wing, Minnesota, December 27, 1855, and spent his boyhood on a farm. He studied at Carleton College, Northfield, and received his medical training at Hahnemann Medical College in Chicago, graduating in 1883.

Upon graduation Dr. Spates began practice at Milbank, South Dakota, but in May, 1884, moved to Saint Paul. On September 29, 1883, he was married to Carrie Belle Williams of Saint Paul. A resident of Dayton's Bluff, he served the Bluff area and outlying communities in Hazel Park, North Saint Paul, Highwood and Newport for fifty-two years. His was the sacrificial life which characterized the old-time family physician in the days when the horse and buggy were the means of travel. During his lifetime he did much obstetrical work.

Dr. Spates was a charter member of the East Presbyterian Church and was active in the Arlington Hills East Presbyterian Church with which it merged. He was a staunch Christian and carried out Christian principles in his medical practice as well as in his social and home life. He loved children and they constituted a large portion of his patients. He liked people and in turn was loved by his patients.

Dr. Spates is survived by his widow, two sons, Dr. Kenneth C. Spates of Saint Paul and Leland W. Spates of Van Nuys, California; two daughters, Mrs. R. L. Faulkner and Eleanor F. Spates of Saint Paul.

Thomas Lowe

1858-1939

DR. THOMAS LOWE, of Pipestone, Minnesota, for several years a member of the State House of Representatives, died, following an attack of influenza, March 12, 1939, at the West Side Hospital, Saint Paul.

Dr. Lowe was born at La Chute, Quebec, Canada, November 8, 1858. When he was thirteen years of age, his family moved to the United States and located in Bremer County, Iowa. In 1877, the family moved to Murray County, where the father and three of his sons took up homesteads.

After attending school in Decorah, Iowa, Dr. Lowe taught school for a few years and then attended Hahnemann Medical College in Chicago, from which he was graduated in 1885. Upon receiving his medical degree, he returned to Murray County to practice, opening an office at Slayton. It was here that he met Sadie Southwell, who became his wife, on June 18, 1887. In 1904, the Lowes moved to Pipestone, where Dr. Lowe has since practiced.

In 1937, Dr. and Mrs. Lowe celebrated their golden wedding anniversary.

Throughout his long life, Dr. Lowe took an active interest in local and state politics. He was five times mayor of Pipestone. He served as commissioner of the Southwestern Minnesota Tuberculosis Sanatorium, and served on the Minnesota State Board of Medical Examiners for twenty years. He was a member of the Masonic, Woodman, Yeoman, and Knights of Pythias orders. When taken fatally ill, he was serving his second term in the House of Representatives and was very active in spite of his advanced age.

Doctor Lowe was the seat-mate of the only other physician in the House, Wm. J. Eklund, of Duluth. Dr. Lowe was chairman of the Committee of Public Health and Hospitals and represented his county on the important Appropriations Committee. Always fair and considerate, he was loved and respected by all members of the House. His clear thinking and ability came from his long service in the practice of medicine.

While actively engaged in the above-named organizations, he yet found time to take several postgraduate courses in New York; at one time serve as president of his local society, the Southwestern Minnesota Medical Society; and hold memberships in the Minnesota State and American Medical Associations.

Surviving Dr. Lowe are Mrs. Lowe and four children: Mrs. Raymond Hughes of Mankato; Margaret of Pipestone; William of Saint Paul; and Duncan of Weslaco, Texas.

MEDICAL BROADCAST FOR MAY

The Minnesota State Medical Association Morning Health Service

The Minnesota State Medical Association broadcasts weekly at 11:00 o'clock every Saturday morning over Station WCCO, Minneapolis (810 kilocycles or 370.2 meters) and Station WLB, University of Minnesota (760 kilocycles or 395 meters).

Speaker: William A. O'Brien, M.D., Associate Professor of Pathology and Preventive Medicine, Medical School, University of Minnesota. The program for the month will be as follows:

May 6—Prenatal Care
May 13—First Year of Life
May 20—Prematurity
May 27—Prenatal Care of Teeth

MINNESOTA STATE MEDICAL ASSOCIATION

Eighty-sixth Annual Session

May 31, June 1 and 2, 1939

Minneapolis, Minnesota

Officers and Committees

President—George Earl	St. Paul
Past President—J. M. Hayes	Minneapolis
First Vice President—J. C. Jacobs	Willmar
Second Vice President—A. M. Hanson	Faribault
Secretary—B. B. Souster	St. Paul
Treasurer—W. H. Condit	Minneapolis
Speaker, House of Delegates—W. W. Will	Bertha
Vice Speaker, House of Delegates—E. A. Meyerding	St. Paul
Executive Secretary—Mr. R. R. Rosell	St. Paul

Committee on Scientific Assembly

George Earl, President	St. Paul
J. M. Hayes, Past President	Minneapolis
Mr. R. R. Rosell, Executive Secretary	St. Paul

Section on Medicine

J. Allen Wilson	St. Paul
J. A. Myers	Minneapolis
B. O. Mork, Jr.	Worthington

Section on Surgery

V. S. Counseller	Rochester
F. H. Magney	Duluth
Charles Bolsta	Ortonville

Section on Specialties

W. A. O'Brien	Minneapolis

Committee on Local Arrangements

General Chairman—A. E. Cardle

General Advisory—George D. Head, W. H. Aurand, Moses Barron, James Blake, J. F. Corbett, J. A. Watson

Banquet—Gilbert Thomas, C. E. Arlander, F. R. Hirshfield, F. J. Kucera, D. A. MacDonald, H. F. Wahlquist

Commercial Exhibits—T. H. Sweetser, Ruth Boynton, W. R. Jones, E. J. Lillehei, W. G. Schaefer, Nora Winther

Golf—H. M. Lee, A. E. Benjamin, L. R. Boies, R. R. Cranmer, L. O. Doyle, E. G. Nylander

Hotel Reservations—H. W. Christianson, F. G. Benn, E. J. Borgeson, H. E. Hoffert, F. B. Mach, O. F. Robbins

House Arrangements—C. C. Kennedy, A. N. Bessesen, Jr., C. O. Hansen, A. B. Johnson, M. E. Knapp, J. T. Lapierre, J. H. Taylor

Public Relations—Gilbert Cottam, H. S. Diehl, F. E. Harrington, A. J. Herbolsheimer, F. A. Olson, T. W. Weum, S. M. White

Reunions—H. G. Scott, S. L. Arey, H. G. Benjamin, Reuben Erickson, W. A. Fansler, R. R. Knight

Scientific Exhibits—C. A. McKinlay, P. A. Anderson, R. P. Caron, T. J. Kinsella, M. C. Pfunder

---

Announcements

Luncheons.—Twenty Round Table Luncheons have been arranged at the Hotel Curtis for this meeting, ten on Wednesday, May 31, and ten on Thursday, June 1. List of subjects and leaders for these luncheons have been sent to all members. Tickets must be purchased in advance for these luncheons. Attendance at each luncheon is limited to 20 and late comers will be accommodated according to their choice if limits have not already been reached. Price of luncheon tickets, $1.00.

Public Health Exposition.—The first Public Health Exposition ever sponsored by the Minnesota State Medical Association will open in the Auditorium basement Wednesday, May 31, and close Saturday, June 3. Admission will be by ticket but without entrance fee. Hours: 10 a.m. to 10 p.m. Special tours have been arranged during the day for the Minneapolis school children. Public Health lectures and moving pictures on popular subjects are scheduled each afternoon and evening. The Minnesota Department of Health, the Minneapolis City Health Department, the University of Minnesota and other official and voluntary welfare agencies are coöperating with the Minnesota State Medical Association in this Exposition. Every physician is urged to view this Exposition as well as the Scientific and Technical Exhibits on the floor above.

Annual Banquet.—The annual dinner for members and their wives will be held in the Auditorium, Thursday evening, June 1, at 7:30 p.m. Governor Harold E. Stassen will give the banquet address. Entertainment arranged by the Hennepin County Medical Society will follow the dinner.

The Southern Minnesota Medical Association will present a medal, following its annual custom, to the individual physician who presents the best scientific exhibit at this meeting. Judges will be selected from among distinguished out-of-state visitors. The award will be made at the Annual Banquet at the Hotel Curtis Thursday evening.

Golf Tournament.—The annual Golf Tournament will begin Friday at 1 p.m. at the Interlachen Country Club. Registration for the tournament should be made at the Registration Desk. Entrants may make up their own foursomes or apply to the Chairman, H. M. Lee, 1427 Medical Arts Building, Minneapolis, for partners. Attractive prizes have been donated for the winners.

Fracture Dinner.—One representative from each county and district society has been invited to attend a dinner at 6:30 p.m. Wednesday for the purpose of organizing fracture committees in each component medical society in the state. Charles L. Scudder of Boston will talk on "Duties of a Local Fracture Committee."

Fracture Meeting 8 P. M.—Following the dinner, Dr. Scudder will address a meeting in the East Room of the Hotel Curtis on "Fractures as a State Medical Association Problem." Open to all physicians.

The Minnesota Radiological Society will give a dinner at 6:30 p.m. Wednesday, May 31, at the Hotel Nicollet in honor of W. Edward Chamberlain of Philadelphia. Dr. Chamberlain will give the Russell D. Carman Memorial Lecture at 4 p.m. Wednesday.

The Trudeau Society will hold a dinner meeting Wednesday, May 31, 6:30 p.m. at the Hotel Nicollet. Dr. Robert G. Bloch, Chicago, whose appearance on the Thursday afternoon program is sponsored by the society, will be the principal speaker.

An American College of Surgeons breakfast will be held Friday morning at 7:30 a.m. at the Hotel Curtis. Members from Minnesota and adjacent states are invited to attend. Dr. Malcolm T. MacEachern, Chicago, Associate Director of the American College of Surgeons, will speak.

Visiting Speakers

Rock Sleyster, Wauwatosa President-elect of the American Medical Association, Medical Director Milwaukee Sanitarium.

Andrew C. Ivy, Chicago, Nathan Smith Davis Professor of Physiology and Pharmacology. Head of the Division at the Medical School of Northwestern University. Consultant Passavant Hospital, Chicago. Sponsored by the Northern Minnesota Medical Association.

Joseph Stokes, Jr., Philadelphia, Associate Professor of Pediatrics, University of Pennsylvania School of Medicine. Sponsored by the Northwestern Pediatric Society.

W. Edward Chamberlain, Philadelphia, Professor Radiology and Roentgenology, Temple University School of Medicine. Sponsored by the Minnesota Radiological Society. Dr. Chamberlain will deliver the annual Russell D. Carman Memorial Lecture.

Charles L. Scudder, Boston, Consulting Surgeon to the Massachusetts General Hospital. Formerly Assistant Professor of Surgery, Harvard Medical School.

Everett D. Plass, Iowa City, Professor of Obstetrics and Gynecology, State University of Iowa, College of Medicine.

Thomas Francis, Jr., New York, Professor of Bacteriology, New York University, College of Medicine. Sponsored by the Minnesota Society of Internal Medicine.

Robert G. Bloch, Chicago, Associate Professor Medicine, School of Medical Division of Biological Sciences, University of Chicago. Sponsored by the Trudeau Society.

F. W. Jackson, Winnipeg, Deputy Minister Health and Public Welfare of Manitoba.

Monsignor Maurice F. Griffin, Cleveland, Catholic Hospital Association.

Mr. J. G. Crownhart, Madison, Executive Secretary of the State Medical Society of Wisconsin.

The Honorable Henrik Shipstead, United States Senator.

Assistant Surgeon General C. E. Waller, Washington, United States Public Health Service.

BUSINESS PROGRAM

Hotel Curtis

Tuesday, May 30

4:00 P.M.	Council	Room B
4:00 P.M.	Reference Committees	
8:00 P.M.	House of Delegates	East Room

Wednesday, May 31

7:30 A.M.	Council	Room B
12:15 P.M.	House of Delegates	East Room

Thursday, June 1

7:30 A.M.	Council	Room B
5:00 P.M.	Installation of Officers Report of Secretary	Auditorium

SCIENTIFIC PROGRAM

Wednesday, May 31

Morning Session—8:30 A. M.

Scientific Cinema
  Scaleniotomy for Cervical Rib
    Alton Ochsner, New Orleans
Announcements
    George Earl, St. Paul
Complete Fracture Demonstrations, Patients, Histories, Slides and X-rays
    O. W. Yoerg, Minneapolis
    V. P. Hauser, St. Paul
    H. W. Meyerding, Rochester
Scientific Cinema
  Some Practical Pointers on the Treatment of Intra-Capsular Fractures of the Neck of the Femur
    W. D. White, Minneapolis
    E. C. Henrikson, Minneapolis
Bile Salt Therapy in Gall Bladder Disease
    Andrew C. Ivy, Chicago
Headaches
    H. W. Woltman, Rochester
Treatment of the Mental Defective
    E. J. Engberg, Faribault

Round Table Luncheons—12:15 P. M.

Newer Drugs
  Leader—R. N. Bieter, University of Minnesota
Surgery of the Stomach (Indications for Various Procedures)
  Leader—W. C. Carroll, St. Paul
Surgery of the Small Bowel
  Leader—O. H. Wangensteen, University of Minnesota
Treatment of Sterility
  Leader—C. J. Ehrenberg, Minneapolis
Operative Treatment of Fractures
  Leader—Charles L. Scudder, Boston
Peptic Ulcer
  Leader—Andrew C. Ivy, Chicago
Allergy
  Leader—R. V. Ellis, University of Minnesota
Methods of Immunization Against Acute, Contagious and Infectious Diseases
  Leader—Joseph Stokes, Jr., Philadelphia
Treatment of Medical Emergencies
  Leader—H. E. Richardson, St. Paul
Roentgenography of the Chest
  Leader—W. Edward Chamberlain, Philadelphia

Afternoon Session—1:30 P. M.

Scientific Cinema
  Metrazol Treatment for Psychoses
    G. N. Ruhberg, St. Paul
Treatment of Mycotic Dermatitis
    H. E. Michelson, Minneapolis
Treatment of Atopic Dermatitis
    E. M. Rusten, Minneapolis
Diagnosis and Treatment of Hemorrhagic Diathesis
    C. H. Watkins, Rochester
Studies of Certain Respiratory Infections of Virus Origin
    Joseph Stokes, Jr., Philadelphia
Scientific Cinema
  Advances in Brain and Cord Surgery
    A. W. Adson, Rochester
Russell D. Carman Memorial Lecture
  Low Back Pain
    W. Edward Chamberlain, Philadelphia
Introduction: W. H. Ude, Minneapolis

Evening Session—8:00 P. M.

Fracture Meeting
  Presiding Officer, F. J. Elias, Duluth, Chairman Fracture Committee
Fractures as a State Medical Association Problem
  Charles L. Scudder, Boston

Thursday, June 1

Morning Session—8:30 A. M.

Scientific Cinema
  Inlying Graft for Hypospadias
    V. S. Counseller, Rochester
Causes of Uterine Bleeding
    J. L. McKelvey, University of Minnesota
Pelvic Pain
    W. A. Coventry, Duluth
Adenomyomata
    W. G. Benjamin, Pipestone
Treatment of Vaginal Discharges

PICROTOXIN TREATMENT OF BARBITURATE INTOXICATION

(Continued from Page 310)

Conclusions

1. Animal experimentation and clinical trial have established some justification for the cautious use of picrotoxin in barbiturate poisoning.

2. In the presence of a known case of barbiturate intoxication, picrotoxin may be safely administered intravenously at the rate of 1 mg. per minute, for a total dosage of 9 mg. to 12 mg. at intervals of one-half hour to four hours.

3. The case here reported showed the first signs of return of consciousness when the "barbiturate equivalent" of picrotoxin had been administered.

4. The customary supportive measures must be carried out while treating barbiturate intoxication with picrotoxin and in addition each case must be observed closely and dosage of picrotoxin gauged according to clinical signs and response of the individual case.

FIELD CLINICS FOR CRIPPLED CHILDREN

Orthopedic surgeons from the Minnesota-Dakota Orthopedic Club are coöperating with the Division of Services for Crippled Children of the State Board of Control by serving again this year as orthopedic consultants at the field clinics for crippled children which are conducted annually by the Division. The first clinic of the spring series was held April 15 in St. Cloud with Drs. E. T. Evans and M. O. Henry, both of Minneapolis, as examining orthopedic surgeons. Drs. J. F. Pohl and J. H. Moe, also of Minneapolis, were in charge of the Morris Clinic, which was held April 22. The schedule for the remaining five clinics follows:

Willmar Clinic, April 29—Dr. V. L. Hart, Minneapolis; Mayo Clinic orthopedic surgeon.

Crookston Clinic, May 13—Dr. G. A. Williamson, Saint Paul; Dr. J. R. Kuth, Duluth.

Austin Clinic, May 20—Dr. C. C. Chatterton, Saint Paul; Mayo Clinic orthopedic surgeon.

Detroit Lakes Clinic, June 3—Dr. G. A. Williamson, Minneapolis; Dr. Wm. H. Von der Weyer, Saint Paul.

Aitkin Clinic, June 10—Dr. S. W. Shimonek, Saint Paul; Dr. M. H. Tibbetts, Duluth.

The purposes of field clinics for physically handicapped children in the state is to find new cases, to follow up old cases, to emphasize preventive health education, and to provide consultation services for the local family physician for his indigent crippled children patients. All physically handicapped persons under twenty-one years of age who cannot provide private medical care are eligible upon presenting a letter of referral from their family physician.

Coöperating also with the Division of Services for Crippled Children is the Division of Vocational Rehabilitation of the State Department of Education, which sends an expert from its staff to each clinic to give vocational guidance, and the Minnesota Public Health Association, which coöperates with the preliminary educational program.

RED RIVER VALLEY SOCIETY

Members of the Red River Valley Medical Society and their wives, numbering fifty-five, including a delegation from Thief River Falls, assembled at the Hotel Crookston Tuesday night for the annual dinner meeting of the society, followed by separate business sessions for the physicians and their auxiliary.

The meeting for the auxiliary held at the home of Mrs. G. A. Morley, was the annual business session, with election of officers and preparation of the group's report for the state medical auxiliary meeting next month. Mrs. S. H. Stuurmans of Erskine was named president of the auxiliary, succeeding Mrs. Baldwin Borreson, with Mrs. H. M. Blegen of Warren first vice president; Mrs. G. W. Hohl of Ada, second vice president; Mrs. D. V. Boardman of Twin Valley, recording secretary; Mrs. H. H. Hedemark of Thief River Falls, corresponding secretary; and Mrs. C. L. Oppegaard of Crookston, treasurer.

The joint session of the physicians and their wives was featured by an address by Mrs. Virginia Liebeler, state director of the Minnesota Hospital Service Association.

After members of the auxiliary had adjourned to the home of Mrs. Morley, physicians heard an address by A. W. Aamodt, state supervisor for the Farm Security Administration, on the medical problem presented by the low income groups, operating on borrowed government capital and under the supervision of the FSA.

The meeting for physicians was concluded with the showing of three scientific films.

MINNESOTA HOSPITAL ASSOCIATION

The sixteenth annual meeting of the Minnesota Hospital Association will be held Thursday, Friday and Saturday, May 25, 26 and 27, 1939, in the St. Paul Hotel, St. Paul, Minnesota. Dr. Peter Ward, Saint Paul, president of the association, will preside. Thursday morning will be devoted to registration and a meeting of the Board of Directors. The regular business session will occupy the Thursday afternoon meeting, to be followed at 6:00 P. M. with a buffet supper at St. Joseph's Hospital.

Scientific papers presented by leading hospital authorities covering the different departments in a well organized hospital will occupy the session Friday morning. A noon luncheon at the Lowry Hotel will be addressed by B. W. Caldwell, M.D., Executive Secretary, American Hospital Association; M. T. McEachern, M.D., Associate Director, American College of Surgeons and President, International Hospital Association; and R. C. Buerki, M.D., President, American College of Hospital Directors.

Friday afternoon the following allied organizations will hold sessions: Minnesota Association of Nurse Anesthetists, Minnesota Dietetic Association, Minnesota Chapter—National Executive Housekeepers' Association, Minnesota Association of Hospital, Medical and Institution Librarians, Minnesota Society of Medical Technologists, Minnesota Occupational Therapy Association, Minnesota Chapter American Physiotherapy Association, Minnesota Record Librarians' Association. A General Session at 3:30 P. M. will consist of a round table discussion led by R. C. Buerki, M.D.

At the annual banquet to be held Friday evening the speakers will include Basil McLean, M.D., Superintendent, Strong Memorial Hospital, Rochester, New York; George Earl, M.D., President Minnesota State Medical Association; and Honorable Harold E. Stassen, Governor of Minnesota.

The meeting Saturday morning will include addresses on various phases of hospitalization to be followed by the final business session. A golf tournament at the White Bear Yacht Club will conclude the program in the afternoon.

# ◆ WOMEN'S AUXILIARY ◆

MRS. W. B. ROBERTS, Minneapolis, *President*
MRS. E. V. GOLTZ, 2259 Summit Avenue, Saint Paul, *Publicity Chairman*

The Annual State Convention which will be held in Minneapolis May 31 to June 2, inclusive, should draw many members from the various county auxiliaries. Registration will open May 30 from 4 to 6 p. m. at the Curtis Hotel and the following morning at 9 a.m. at the Curtis Hotel. Wednesday morning, May 31, the pre-convention executive board meeting will be held at the Leamington Hotel with a luncheon following for members of the board only. From 3 to 5 p. m. that day the members of the Hennepin County Auxiliary will entertain all auxiliary members at a tea in the Hennepin County rooms on the 20th floor of the Medical Arts Building. The evening will be devoted to the scientific and allied health displays in the Municipal Auditorium. Thursday, June 1, the annual State Auxiliary meeting will be held at 10 a. m. at the Interlachen Country Club. Those wishing to attend this meeting will find cars awaiting them at the Curtis Hotel at 9:15. A luncheon will be held at Interlachen following the meeting and cars will start from the Curtis Hotel at 12 o'clock noon for those who wish to attend the luncheon and not the annual meeting in the morning. At 6:30 p. m. members of the auxiliary will meet with the doctors at dinner at the Leamington Hotel. Friday, June 2, a sightseeing trip with a visit to the Sibley House at Mendota where luncheon will be served will conclude the convention program. Cars will leave the Curtis Hotel at 11 a. m. and will return guests to the hotel after luncheon. Hennepin County extends a very cordial invitation to all members to attend and it is hoped that there will be a large attendance.

* * *

Our state president, Mrs. Wm. B. Roberts, presided at the recent meeting of the Women's Field Army of the American Society for the Control of Cancer, held in Saint Paul. "Civilization Against Cancer" was the theme of the meeting. The Winona Auxiliary, of which Mrs. C. P. Robbins is president, received recognition for their contribution to the fund for Control of Cancer at this meeting. This was the project of the Winona Auxiliary for their activity this year.

* * *

The seventeenth annual convention of the national Auxiliary will be held at the Hotel Chase, St. Louis, Missouri, May 15 to 19 inclusive. Registration will be held from 10 a. m. to 4 p. m. Sunday, May 14, with a tea in the afternoon for the national board in honor of Mrs. Charles C. Tomlinson, president. Monday, May 15, the national board meeting will be held in the Empire Room, Hotel Chase, at 9 a. m., and from 1:30 to 4:45 p. m. there will be a tea at the private gardens of St. Louis County. Tuesday, May 16, the formal opening of the convention and general session will be held in the Empire room of the Hotel Chase from 9 a. m. to 12 noon with luncheon at the St. Louis Woman's Club at 12:30, followed by tours with a tea at the St. Louis University Woman's Club at 4 p. m. The opening meeting of the American Medical Association will be at 8 p. m. in the Municipal Auditorium. Wednesday, May 17, there will be a general session at 9 a. m. at the Chase Hotel with auxiliary luncheon at 1 p. m. at the Chase Club, followed by exhibits and music and conferences. A reception will be held that night for all visiting ladies with a motion picture revue of United States Seal fisheries and a fur fashion show. Thursday, May 18, the post-convention executive committee meeting will be held at 9 a. m. followed by the post-convention Board of Directors meeting. From 12:30 to 3:30 in the afternoon there will be a Mississippi steamboat trip for men and women and at 7 p. m. the annual "Bring Your Husband" dinner at the Chase Hotel, followed by a reception in honor of the president of the American Medical Association at the Hotel Jefferson. A Woman's Golf Round and Blind Bogey with trophies and prizes will be the feature for Friday, May 19, the closing day. It is hoped that Minnesota will be well represented at the annual national meeting.

* * *

Mrs. Leo Crafts of the Hennepin County Auxiliary passed away April 13, in Minneapolis. Her home was at 610 Fifth Street S. E. Mrs. Crafts was prominently identified with Auxiliary affairs, having served as president of the Hennepin County Auxiliary, and was a member of the Revision Committee of the State Auxiliary at the time of her death. She had spent the past fifty years as a resident of Minneapolis and was an instructor in Art at the State University from 1889 to 1901. She studied art in the East under a group of well known teachers including Edmund Tarbel, Joseph De Camp and Roda Holman Nichols, and she was a member of the Fine Arts Club of Boston, Fine Arts of Minneapolis, Women's Club and a member of the board of directors of the Y.W.C.A. and Travelers Aid. Many members of the auxiliary will remember the lovely poster she completed for the Hennepin County Auxiliary. She was an extensive traveler, having spent much time in Europe. Sincerest sympathy is extended to her family.

* * *

The Ramsey County Auxiliary recently voted to give $100 to a fund to provide an Infantile Paralysis Center in Ramsey County. The annual reciprocity tea was given Monday, April 27, in the Ramsey County Library rooms. Dr. George Earl spoke on "Phases of Socialized Medicine." Mrs. Donald Bacon read the play "Kiss the Boys Good-bye." Invitations had been extended to various women's organizations to attend. Mrs. Wm. B. Roberts, State President, was a guest. Tea was served to seventy guests following the program.

BOOK REVIEWS

Books listed here become the property of the Ramsey, Hennepin and St. Louis County Medical libraries when reviewed. Members, however, are urged to write reviews of any or every recent book which may be of interest to physicians.

YOUR CHEST SHOULD BE FLAT. F. A. Weisman, M.D., F.A.C.P. Assistant Professor of Medicine, University of Minnesota; Member of Consulting Staff, Glen Lake Sanatorium, Oak Terrace, Minnesota; Member of Staff of St. Andrew's and St. Mary's Hospitals, Minneapolis. 145 pages. Illus. Price, cloth, $2.00. Philadelphia: J. B. Lippincott & Co., 1939.

In a small volume Dr. Weisman has presented the results of his studies of thoracic indices of 20,000 school children as well as smaller groups of tuberculous individuals and preventorium children. From this material he has arrived at a normal thoracic index, that is, the ratio of the antero-posterior to the lateral dimensions of the chest through infancy, childhood and adult life. He has shown that the individual who on casual examination appears to be flat chested is very likely actually to be deep chested, that is, to have a high thoracic index, and that the appearance is due to postural differences rather than to actual flattening of the chest. While Dr. Weisman has found that the thoracic indices of young adults having tuberculosis are higher than those of similar groups of healthy individuals, he also has very clearly shown that this index is an indication of malnutrition and under-development. His study of the school children in Minneapolis shows a higher thoracic index in the children coming from poorer districts than in those coming from the more well-to-do parts of the city.

It is a recognized fact that prevalence of open tuberculosis is greater in neighborhoods of lower economic strata. It seems to me that Dr. Weisman's thesis, "that the deep chest makes better soil for tuberculosis," is based on the corollary that tuberculosis is more prevalent in the lower economic level, that malnutrition and under-development are more prevalent in the same strata and that the majority of individuals with deep chest, i.e., high thoracic indices, will come from such an environment. Therefore, the person with the deep chest is more apt to have tuberculosis. This book should be a valuable addition to the library of physicians, physical education directors, social service workers and teachers in emphasizing the problem of malnutrition and in presenting a simple method for indicating such condition.

G. A. Hedberg, M.D.

AN EFFECTIVE TREATMENT FOR

TRICHOMONAS VAGINITIS

An effective treatment by Dry Powder Insufflation to be supplemented by a home treatment (Suppositories) to provide continuous action between office visits. Two Insufflations, a week apart, with 12 suppositories satisfactorily clear up the large majority of cases.

JOHN WYETH & BROTHER, INC. • PHILADELPHIA, PA.

PAGES' PERIDURAL ANESTHESIA*

A Report of 3,826 Cases

DR. VICENTE RUIZ
Buenos Aires, Argentina

SINCE the beginning of 1932, and for the first time in Argentina, we have been carrying out experiments at this clinic with a new anesthetic method, epidural or peridural anesthesia. This technic was devised in 1920 by a Spanish surgeon, Dr. Fidel Pagés. Since Pagés died prematurely and was able to publish only one paper, in 1921 (Revista Española de Cirugia) recording the results he obtained in forty-three cases, this new method passed almost unnoticed. A few years ago, however, Prof. Dogliotti,[3,4] of Prof. Uffreduzzi's clinic at Torino, described a technic bearing a remarkable similarity to that of Dr. Pagés'.

It should be mentioned that other investigators had previously tried a similar procedure, but their results were unsatisfactory. Among them was Corning, who in 1885 endeavored to modify spinal anesthesia, but without success. Later, Sicard (1901) and then Cathelin, advocated the use of epidural injections of anesthetics for therapeutic and surgical purposes, but they followed the sacral route and sought only to anesthetize the lowest spinal nerves. Other surgeons such as Laewen (1910), Tuffier, Reclus, Chipault, Hamecart, Schlimpert, Pauchet, Kroning, Schneider, Kehrer (1916), Stoeckel, and Bleek, injected sacrally larger quantities of anesthetic with a view of obtaining a higher zone of anesthesia. Some of these workers, besides performing epidural anesthesia, injected veronal, morphine, and scopolamine. This brief historical survey is important in that it will prevent one from mistaking Cathelin's sacral epidural anesthesia for the method we are about to describe. The former method is not used for operations in the abdomen, thorax, neck and limbs as is the latter.

The results obtained by the foregoing surgeons were on the whole unsatisfactory, as has already been stated. Epidural anesthesia fell therefore into disuse because of its irregular results and several fatal accidents. The technic conceived by Pagés surpasses the others in so far as it does away with the need for preliminary medication, is generally always harmless and yields consistent results.

At this point it is well to recall that there is no communication between the peridural and subarachnoid spaces, so that an anesthetic injected into the former cannot cause bulbar accidents. Besides, it should be borne in mind that the peridural space has a negative pressure, to which the "drop sign," to be described later, is due.

Technic

We use at this clinic an ordinary 10 cm. syringe, and a long, thin needle with a short bevelled edge, which was designed by Prof. Gutiérrez. The anesthetic employed is 1 per cent procaine (novocain) solution which is prepared at the moment of the operation; 1.20 grains of Bayer's, previously tyndallized, crystallized procaine is diluted in a wide-necked graded flask containing 60 c.c. of sterile physiologic saline solution. To this solution 10 drops of 1:1000 epinephrine solution are added; this delays absorption of the anesthetic by tightening the vessels, thus facilitating a more prolonged contact of the anesthetic with the spinal nerves.

---

*From the Clinic of Prof. Alberto Gutiérrez, Spanish Hospital, Buenos Aires, Argentina.

After trying several solutions we have definitely adopted the 2 per cent solution because of its effective results and safety. When the anesthetic solution is ready we inject it with the patient in a sitting or lateral decubital position on the operating table. The former position is preferable, the latter being used only exceptionally (in the case of high-strung nervous patients, and so forth).

The technic followed in the first part of peridural anesthesia is just the same as that for spinal anesthesia; the spinous processes are palpated and the puncture is made medially or laterally. We prefer the middle line for the following reasons: (1) the peridural space is wider here, that is to say, there is a greater space between the dura mater and the yellow ligament, the endorachid veins, which are on the sides, are less likely to be injured, and (3) it is easier to make the puncture.

Site of puncture.—Experience has indicated that it is immaterial whether the puncture is made between the first and second lumbar vertebra, between the second and third, or between the third and the fourth; the last, however, is the zone we generally always choose. Puncture may also be made in the lower part of the thoracic column, but this we have seldom tried. By making the puncture between any of the lumbar vertebræ, anesthesia is produced that extends from the clavicle to the lower limbs, because when the solution spreads through the peridural space it reaches the spinal nerves. However, if only a small area of anesthesia is desired (it should be remembered that this anesthesia is metameric, and we can consequently choose the places where to make it), we should bear in mind the vertebroradicular and vertebromedullary topography and the fact that the innervation of the abdominal or thoracic wall does not correspond with the innervation of the viscera.[5]

"The drop sign."—After piercing the skin and the subcutaneous tissue with the needle and its mandrin, we reach the supraspinous ligament. Before continuing the puncture we withdraw the mandrin, take the syringe filled with the anesthetic solution and try to inject the liquid. Naturally, resistance is offered by the supraspinous ligament which hinders the entrance of the liquid; the syringe is then withdrawn and the liquid remains, filling the needle and its pavilion. We proceed now to drive the needle in, millimetrically, being careful that the thumb and forefinger do not cause the drop remaining in the pavilion to fall. The needle penetrates the supraspinous ligament; then the interspinous ligament and last the yellow ligament; this is felt, more or less clearly, with the fingers. When the tactile sensation is perceived (and sometimes there is a slight click, too), the drop is absorbed, sucked in by the negative pressure of the peridural space. Thus we are sure that the end of the needle is in the space. This fact was observed, for the first time by Prof. Gutiérrez, who called it the "drop sign." This sign, which is noticed in most cases, renders the technic of peridural anesthesia easier and places it within reach of a greater number of surgeons. The drop may be absorbed rapidly or slowly; in a few instances it suffers only a slight oscillation. At this moment the syringe filled with anesthetic solution is applied to the needle and it is seen that, when driving the piston, the liquid penetrates without difficulty, just as when making an intravenous injection, for instance.

When the point of the needle enters the yellow ligament it may happen that instead of the drop being absorbed, cerebrospinal fluid flows out; this may be due to two factors: (1) excessive penetration of the needle, or (2) the dura mater may adhere to the wall of the rachis, and the peridural space may be reduced to a minimum or may have disappeared. If the flow of cerebrospinal fluid is due to excessive penetration of the needle, which has perforated the dura mater the needle is withdrawn millimetrically, and, when the liquid stops flowing, we test with the mandrin to see that the needle is not obstructed. Then the patient is required to cough. Finally one can still make a further test by aspirating with the empty syringe. After all these tests have been carried out it is safe to begin the anesthesia. It may also happen that when driving the needle in it will come up against a vertebra, or owing to puncture of a vein, blood may flow; in both instances the needle should be withdrawn partially or totally and puncture should be begun anew.

From the foregoing it may be concluded that there are two ways of injecting procaine solution: a direct and an indirect way. Injection is direct when the needle is introduced into the peridural space only, and indirect when it is introduced into the subarachnoid space, as in spinal anesthesia. As soon as cerebrospinal fluid flows, the needle is withdrawn a few millimeters until the fluid stops flowing, thus indicating that the point of the needle has remained in the peridural space.

Once it is certain that the needle is in the peridural space, injection of the anesthetic is begun, usually by the fractional method, as we shall explain later. It is obvious that the direct way is preferable and we follow it in most cases.

The distance to which the needle penetrates before it reaches the peridural space varies greatly with different patients, since it depends on various anatomic factors; the extreme figures we have recorded range between 2 and 8 cm.

We consider the technic employed by us better than the one recently described by Dogliotti. The Torinese professor uses 30 to 60 c.c. of 1 to 1.5 per cent procaine solution, and he appears to prefer the lateral decubital position in making the injection and he does not seem to be acquainted with the "drop sign." He follows a method of reaching the peridural space which we do not deem absolutely without danger. Moreover we disagree with him when he says that peridural anesthesia should not be used for major operations on interior genital organs; our statistics in this respect are conclusive and prove otherwise.

Amount of solution to be injected.—From our experience we can state that the amount of solution to be injected and the procedure employed depend on the importance of the operation and the constitution and weight of the patient. For instance, we have performed appendicectomies with only 20 c.c. of a 2 per cent solution of procaine, and many operations with only 35 c.c., but to secure good anesthesia for any of the ordinary gynecologic procedures in the abdomen, however, 40 or 50 c.c. are injected. The solution should be introduced slowly either all at one time or in portions. In the latter case we inject 5 c.c. and then wait five minutes to ascertain the sensibility and motility of the lower limbs. Once we are positive we have not obtained spinal anesthesia the rest of the solution is injected. To those who try peridural anesthesia for the first time, we advise this procedure.

Effects of procaine anesthesia.—The reactions produced by procaine depend to a certain extent on the emotional stability of the patients and any idiosyncracy they may have. In some cases mere puncture of the skin is enough to produce sweating, fainting, pallor, and so forth. Most patients, however, tolerate the injection perfectly and it causes only slight pallor, dryness in the mouth, tachycardia, cardiac erethism and an epigastric beat due to erethism of the abdominal aorta. We are convinced that, provided the injection is well made, it very rarely causes any trouble.

In our clinic we record carefully on the "anesthetic file," all the sensations experienced by the patients. From a study of 500 files we have arrived at the following conclusions regarding modifications in arterial pressure: immediately after the puncture is made the previous maximal arterial pressure increases and the previous minimal pressure decreases, although to a lesser degree. At the end of the operation both maximal and minimal pressure are seen to have diminished in the same proportion. The pulse rate is quickened moderately after anesthesia and a slight increase is observed also at the end of the operation.

After the injection the patient is made to lie down and 0.25 gm. of caffeine is injected. A zone of anesthesia usually appears in the abdomen after some ten minutes, depending on the place where the puncture was made, and gradually this spreads upward and downward, producing insensibility to thermal pain and tactile anesthesia. This zone of anesthesia thus extends from the lower portion of the abdomen, in most cases after forty minutes up to the second intercostal space (and sometimes even up to the chin) and then down to the feet. Before beginning the operation it is usually necessary to wait for twenty-five to thirty minutes, although we have begun appendicectomies, for example, only ten minutes after the injection; this, however, is exceptional.

With the usual dose of 35 to 45 c.c. of procaine solution anesthesia lasts for from an hour to an hour and a half and, as a result of the great muscular relaxation and visceral immobility produced the most varied operations in the abdomen can be performed, so much so that in many cases the operation resembles dissection.

Sensibility to pain is the first thing to disappear, then the sense of touch and of heat. Tendinous and cutaneous reflexes are absent in the anesthetized area as well as visceral sensibility.

In a few cases, traction on the round ligaments, as when doing ligamentopexis, has provoked some transient nausea or vomiting, and this fact, observed from time to time, has shown the need for anesthetizing the solar plexus if absolute abdominal immobility is desired. This can be secured by puncturing between the first and second lumbar vertebræ. This procedure does not in the least interfere with the operation and takes but a short time to carry out.

I would like to emphasize the fact, however, that it is advisable to wait for some time (about twenty minutes) rather than to hasten to operate, as I have seen cases in which the zone of anesthesia increased after the operation was over. Above all it should not be forgotten that it is necessary to wait thirty minutes when operating on the perineum for it takes a longer time to produce anesthesia in this region.

The postoperative condition of the patient is quite satisfactory, since untoward reactions do not follow this method of anesthesia. Nausea and vomiting, which so often afflict those who are operated on by inhalation anesthesia, are reduced to a minimum and the headache and backache which are induced by spinal anesthesia are also absent. In only one case was rachialgia observed, and this only for a day, at the site of the puncture. As this was one of the first cases in which we attempted this form of anesthesia, pain was probably caused by the liquid being introduced in the interspinous or yellow ligaments. The advantages of peridural anesthesia can be appreciated not only during operation, but especially during the postoperative period when patients have undergone long and serious procedures.

Complications.—Before referring to the cases in which this method of anesthesia has been successful and summarizing the results obtained in our clinic in 3,826 cases, I shall dwell at some length on the enlightening and interesting subject of failures and accidents observed when using peridural anesthesia. In this respect we are very strict and class as failure either those cases in which anesthesia was not obtained or those in which it was incomplete or limited as well as when accidents occurred with its use.

In 1932, out of 202 cases, we had twelve failures; in six cases anesthesia was not obtained, while in the rest it was necessary to complete the operation with ether, chloroform, or by local anesthesia. However, of a total of 3,826 cases in which peridural anesthesia was performed, the number of failures was only forty-one, including cases in which only partial anesthesia was obtained.

This small number of failures could certainly be decreased still further by limiting the number of anesthetists, for in Prof. Gutiérrez' Service each surgeon anesthetizes his own patients and even general practitioners do it. Although the technic is not at all difficult, it requires a certain amount of skill which only practice can give. This and the fact that at first we used only a 1 per cent solution of procaine account for most of our early unsuccessful cases.

Failures and accidents with this form of anesthesia are due to various causes: (1) faulty technic, (2) use of too weak a solution, or (3) an insufficient amount of solution. I deliberately do not mention the possibility of some anatomic anomaly that might prevent the complete diffusion of the anesthetic or the fact that the patient may be "raqirresistente," or "spine resistant," as these circumstances might be too often invoked to justify failures. Generally speaking, lack of success can be traced to lack of ability on the part of the anesthetist, ignorance of some of the details of technic and lastly, to some very special instances of ossification of the supraspinous and interspinous ligaments, deviations or deformations of the spinal column, or obesity. Under those conditions even the most skillful anesthetist may fail. In this connection I may say that on two occasions, after having tried in vain to anesthetize the patient, they were left for a later operation, when puncture could be satisfactorily made.

It is to be regretted that some surgeons have tried Pagés' method without first having quite mastered its technic, so that failures and even sudden deaths have occurred. As a result these surgeons have passed an unfavorable judgment on peridural anesthesia apparently forgetting that a gram of procaine cannot be injected into the cerebrospinal fluid with impunity.

In the 3,826 cases in which peridural anesthesia was employed at our clinic we have had two serious accidents caused by the anesthetic and three fatal cases in which we feel certain that death was not caused by anesthesia, as necropsy, had we been able to make it, would have proved. The first case in which death occurred was that of a woman sixty years of age, who had mitral insufficiency. In an operation for hemorrhoids, 35 c.c. of procaine solution was injected; she underwent the operation well but, five minutes afterward, had a heart attack and died. In the second case the patient, fifty years old, had frequent arrhythmia. She had a uterine myoma and her physician refused radiotherapy. Puncture was difficult in this case because the adipose panniculus prevented palpation of the spinous process. Although she received an injection of 45 c.c. of procaine, a great part of the solution very likely remained out of the peridural space, as anesthesia was partial and the patient began to complain when the uterine pedicles were being held with the forceps. Ether was given to suture the abdominal wall and when the aponeurosis was being closed she had a syncopal attack and died. The third case was that of a woman, forty-five years of age, who had intestinal occlusion and peritonitis of forty-eight hours' duration. Death occurred when the abdomen was being sutured.

As to the serious accidents, one happened while Dr. Gutiérrez was giving the anesthetic, in the other I was the anesthetist. In the first case the patient had a hydatid cyst on the upper surface of the liver; puncture was made indirectly, between the third and fourth lumbar vertebræ. Shortly after injection respiratory, and later cardiac, paralysis developed, but this was treated with adequate medication. As this accident has been explained at length in a previous report, I shall note here only that three weeks afterward, the patient was operated on successfully using peridural anesthesia. The second accident was that which befell a patient of mine, a woman forty years of age. She was in an undernourished condition and a Wertheim operation was to be performed. Both ureters were catheterized and puncture was then made with the patient in the left lateral decubital position. The "drop sign" was positive. Forty-seven c.c. of 2 per cent procaine solution had been injected when the patient felt slightly giddy. The pulse was soft but even and had a rate of 85 beats per minute. The maximal arterial pressure was 10 and the minimum 4 c. At this time the patient said in a weak voice that she could not breathe well. The pulse continued soft and regular and the thorax, with the intercostal spaces slightly shrunk, hardly moved. Seeing that the patient did not react to the medication given, we employed artificial respiration for three hours. At the end of two and a half hours, she began to breathe irregularly and intermittently, later deeply and rhythmically. Consciousness came back with the respiratory movements, the conjunctival reflex returned and mydriasis disappeared. All of this time the heart beat regularly, although at times it was difficult to feel the radial pulse. Cyanosis was not observed nor were the limbs cold. When the patient recovered, her pulse was regular and beat at the rate of 63 per minute.

In this case the positive "drop sign" eliminated the possibility of penetration of the anesthetic solution into the subarachnoid space and its mingling with the cerebrospinal fluid. The accident was of a respiratory type: paralysis of the diaphragm and of the intercostal muscles. Was it due to anesthesia of the phrenic nerve, or were the intercostal nerves inhibited at first and did the diaphragm then become fatigued, producing reflex bulbar anoxemia? Shrinking of the intercostal spaces leads us to think the last hypothesis is the true one. Rapid diffusion of the anesthetic liquid into the peridural space in addition to the fact that the patient was in the left lateral decubital position and was in an undernourished condition, must have caused the accident. A month later this patient was operated on successfully using 45 c.c. of procaine solution by the peridural route.

Results*

Our 3,826 patients varied between fifteen and seventy-eight years of age, and underwent a variety of operations, such as, gastrectomy, gastroenterostomy, resection of the intestine, abdominoperineal procedures, appendicectomy, herniorrhapy, cholecystectomy, cholecystostomy, operations for cysts of the liver, nephrocolopexy, nephrostomy, nephrectomy, operations for retroperitoneal tumors, Albee operations with costal graft, osteotomy, amputation, and extirpations of the mammary gland including the pectoral muscles and axillary ganglions.

---

*Editor's Note.—In a letter dated April 17, 1939, at Buenos Aires, Dr. Ruiz writes: "At present, the number of cases in which peridural anesthesia has been used at our Spanish Hospital, is over 5,300."

Of the 962 gynecologic operations performed up to May 1, 1937, 735 were by the abdominal route, 227 by the vaginal route.[18] While we have performed every kind of gynecologic operation using this method, for the sake of brevity we will refer only to two cases which afford ample evidence of the advantages of peridural anesthesia. One patient was a woman without a vagina for whom the Baldwin-Mori operation was carried out by Dr. A. Gutiérrez, using 50 c.c. of procaine solution; anesthesia lasted for two and a half hours and only at the end was it necessary to give ether. The patient underwent the operation satisfactorily and the postoperative course was uneventful, her general condition not betraying the intense traumatism she suffered. The other patient had a sigmoid-uterine fistula resulting from abortive attempts five months and a half before entering the clinic; the breach was so large that the woman defecated through the vagina and a cecal anus was made by Dr. A. Gutiérrez for temporary relief; 45 c.c. of procaine solution was injected peridurally. Two months afterward the fistula was closed, although with some difficulty because of adhesions between the sigmoid colon, loops of small intestine and uterus. The operation lasted for an hour and forty minutes and 50 c.c. of solution were injected. The postoperative stage was satisfactory and a month later, the cecal anus was closed using 35 c.c. of procaine solution.

TABLE I. PERCENTAGE OF CASES IN WHICH VARIOUS FORMS OF ANESTHESIA WERE USED

Form of anesthesia	1930	1931	1932	1933
General	68.00%	67.00%	26.20%	4.01%
Local	25.60%	27.00%	35.50%	12.40%
Spinal	3.40%	4.60%	2.50%	0.24%
Miscellaneous .	3.00%	3.40%	4.46%	1.93%
Peridural			30.90%	81.20%

The results obtained with peridural anesthesia are such that, in Dr. Gutiérrez' clinic, it has practically supplanted other anesthetics (Table I).

Conclusions

It is admitted that peridural anesthesia is not perfect, inasmuch as there is some risk attached to its use, but it is equally undeniable that, so far, it seems to be superior to the method of anesthesia commonly used. It is safer than spinal anesthesia because it has all the advantages of that method and none of its disadvantages (bulbar accidents, cephalea, rachialgia, paralysis, vomiting, and so forth). It is better than anesthesia with ether or chlorofrom because it is much less toxic; it may be used in cases when ether or chloroform are contraindicated; it may be repeated without further inconvenience and the postoperative stage is excellent. Local anesthesia is less toxic, but it cannot be used for nervous high-strung patients; it requires greater anatomic skill on the part of the surgeon and a very accurate diagnosis to avoid exploratory maneuvers, and it takes much time—a serious drawback.

We believe that Pagés' peridural anesthesia represents real progress in surgery, although a definite verdict cannot as yet be passed. In the meantime, together with other surgeons in the country who have followed our example, we are gathering experience and data.

THE TREATMENT OF PNEUMOCOCCIC MENINGITIS WITH SULFANILAMIDE AND SPECIFIC SERUM*

Report of a Case with Agranulocytosis and Recovery

ROYAL C. GRAY, M.D., Ph.D.
Minneapolis, Minnesota
and
BLAIR ADAMS, M.D.
Loveland, Colorado

PNEUMOCOCCIC meningitis may be a sequela of pneumonia, middle ear and mastoid and other skull sinus infection, or of skull fracture. It is a rare complication of lobar pneumonia. More frequently it is secondary to otitis media and sinusitis. However, it often occurs entirely independent of any other clinically detectable lesion. The onset is usually acute with high fever, prostration, leukocytosis, and spinal fluid findings such as increased pressure, cell count, and protein, indicative of severe meningeal inflammation. Pneumococci may be identified morphologically in a spinal fluid smear but the accurate and therapeutically proper diagnostic method is by culture and typing. There is no particular distribution of types except a higher frequency of Type III incident to middle ear and mastoid infection.

The mortality in pneumococcic meningitis is practically 100 per cent. In the available American and English literature there are reported less than 100 recoveries in bacteriologically proven cases of this disease. The treatment employed singly or in combination in these cases was: spinal or cisternal-spinal drainage, urotropin, optochin hydrochloride, antimeningococcus serum, sulfanilamide, antipneumococcus serum, M. & B. 693 (sulfapyridine), and no treatment at all.

Satisfactory drainage is difficult since the purulent spinal fluid is usually too thick. Methenamine has only a very questionable general antiseptic value. Optochin hydrochloride has scarcely stood the test of time in the treatment of pneumonia. Antimeningococcus serum certainly cannot be remedial in pneumococcic meningitis. Spontaneous recovery might conceivably occur in any infection but is a forlorn hope in pneumococcic meningitis.

Sulfanilamide has been used effectively in meningitis due to streptococcus hemolyticus, influenza bacillus, meningococcus, and pneumococcus. Neal and Applebaum[9] reported fourteen cases of pneumococcic meningitis treated with sulfanilamide with three recoveries (Types IV, XXIX, and XXXI). The authors called attention to the fact that sulfanilamide penetrates all tissues, is readily absorbed into the general circulation and its concentration in spinal fluid is nearly equal to that in blood a few hours after even oral administration. Three cases of pneumococcic meningitis with recovery have also been reported by Allan, Mayer and Williams.[1] Two of their cases (Types XXIV and XXIX) were treated with sulfanilamide only and one (Type XX) had also repeated spinal drainages but improvement did not appear until a radical frontal sinus operation was done to remove the focus of the infection.

Agranulocytosis may develop as a serious toxic reaction to sulfanilamide. It may be indicated by a secondary rise in temperature and therefore Long and Bliss[8] recommend detailed observation of the patient, careful temperature record, and daily blood studies. Jones and Miller[7] reported one case with recovery and noted that malignant neutropenia may develop suddenly without rash, fever, or any toxic symptom. Johnston[5] compiled from the literature twenty cases of agranulocytosis with six recoveries. The total dose in each case was from 30 to 60 grams. The duration of treatment is more significant as toxic reactions, including agranulocytosis, are more likely if treatment extends past two weeks. Of fifty ambulant patients treated with sulfanilamide by Britton and Howkins,[2] each in a total dosage of 21 grams over a fourteen-day period, 46 per cent developed transient polymorphonuclear leukopenia. The treatment usually recommended for agranulocytosis is pentnucleotide, defibrinated blood transfusions, liver extract, and forced fluids since sulfanilamide is excreted by the kidneys. The complete story of sulfanilamide and similar compounds in chemotherapy has been reviewed by Holman and Duff.[4]

The treatment of pneumococcic meningitis with sulfanilamide alone or in combination with specific antipneumococcic serum is described in an excellent article by Finland, Brown and Rauh.[3] They reported ten cases so treated with six recoveries. These authors caution that highly potent specific serum in any considerable quantity intraspinally might cause a precipitation of the bacteria into clumps and thus mechanically interfere with spinal fluid circulation and drainage. They first prevent or control pneumococcic bacteremia by sulfanilamide orally and subcutaneously and specific serum intravenously. When a balance of specific antibody is thus established in the circulating blood they use the patient's own fresh serum intraspinally.

Recently a new drug, M. & B. 693, first described by Whitby,[13] has been used effectively in England and lately in this country in the treatment of pneumonia and pneumococcic meningitis. Like sulfanilamide, it is a sulfonamido compound but has one hydrogen of the sulfonamido group replaced by a basic pyridine group. It is referred to by the initials of its manufacturing chemists, May & Baker, and its serial number. It has also been termed sulfanilamide-pyridine but is now known as sulfapyridine. Whitby,[12] Reid and Dyke,[10] and Robertson[11] have reported recoveries from pneumococcic meningitis treated with M. & B. 693 (sulfapyridine). Sulfapyridine is bacteriostatic and bacteriocidal, but is capricious and sometimes will not act against a given type or strain of pneumococcus. The drug may precipitate in the kidney as acetylsulfapyridine with resultant hydronephrosis and anuria. Johnson[5,6] has noted agranulocytosis following treatment with this drug which, as with sulfanilamide, is probably due to idiosyncrasy.

Case Report

A nineteen-year-old single Scandinavian farm laborer was admitted to the University of Minnesota Hospital on May 10, 1938. His family and previous personal medical history were entirely negative. Three weeks before admission he had an apparently ordinary sore throat for two or three days and recovered completely. At noon on May 9, when he came in from his usual work in the field he complained of general malaise, chilly sensations, and a severe generalized headache. He had no appetite and went to bed. He seemed sound asleep at supper time and was not disturbed. At breakfast he could hardly be aroused and was forthwith brought to the hospital.

The patient was well developed and well nourished but obviously acutely ill. He was semi-comatose, irrational, restless, and very resistive to examination. The temperature was 102.2 F., pulse rate 100, respirations 22, and blood pressure 130/90. The skin was hot and dry and the face flushed. There was moderate injection of the conjunctivæ and a degree of catarrhal inflammation of both eardrums commensurate with any intracranial infection, but no evidence of suppuration in either middle ear cavity or any skull sinus. Heart, lungs, and abdomen were negative. The bladder was distended with urine. Neurological examination revealed bilateral positive Kernig sign, neck rigidity, slight blurring of both optic discs, and bilateral horizontal nystagmus. The deep reflexes were equal and active and the balance of the examination, in so far as it was possible, was negative. Roentgenograms of the skull and chest were negative.

A blood study was as follows: hemoglobin 77 per cent; red cells 3,500,000; white cells 9100, with neutrophiles 80 per cent and lymphocytes 20 per cent. The blood non-protein nitrogen was 43 mgm. per cent and the sugar 146 mgm. per cent. Urinalysis was negative except for a faint trace of albumen and three plus sugar. Urinalyses were negative throughout on all subsequent examinations.

A lumbar puncture was done one-half hour after admission. The fluid was cloudy, under a pressure of 22 mm. of mercury, and contained 6800 white cells of which 98 per cent were neutrophiles. The total protein was 153 mgm. per cent and the sugar 89 mgm. per cent. The Wassermann reaction and colloidal gold curve were negative. A smear of the spinal fluid revealed no organisms but a culture on blood agar showed a pure strain of pneumococcus Type IV by the Neufeld method of typing.

Treatment with sulfanilamide in a dosage of 80 grains daily in four divided doses was promptly instituted on May 10, the day of admission. The first dose was given with a feeding by stomach tube, the second in a hypodermoclysis, and all subsequent doses orally together with an equal amount of sodium bicarbonate. On May 11, Type IV antipneumococcus rabbit serum was obtained and during that and the next five days the patient received a total of 420,000 units of this serum. The first two doses, each 20,000 units intravenously and 20,000 units intraspinally, were given at two hour intervals. A third single dose of 20,000 units intraspinally was given two hours later. Since the blood culture taken on admission was sterile after eighteen hours incubation, the serum thereafter was given only intraspinally in doses of 40,000 units twice daily for three days and once daily for the next two days. The serum was then discontinued and daily spinal drainages were done until the eleventh hospital day and again on the fourteenth hospital day when the temperature and spinal fluid findings were practically normal. Detailed spinal fluid studies are shown in Table I. After three days of sulfanilamide therapy, 80 grains daily, the blood concentration of the drug was only 3.0 mgm. per cent and therefore the dosage was increased to 100 grains daily. Two days later the level was 5.3 mgm. per cent, well below the therapeutic blood level of 10 mgm. per cent, but since the patient was then vomiting the drug was discontinued for that one day. It was resumed, at 80 grains daily for the following week, then decreased to 40 grains daily for four days, and finally discontinued on the nineteenth hospital day. The essential details of the patient's temperature, pulse rate, therapy, and blood leukocyte counts are shown graphically in Figure 1.

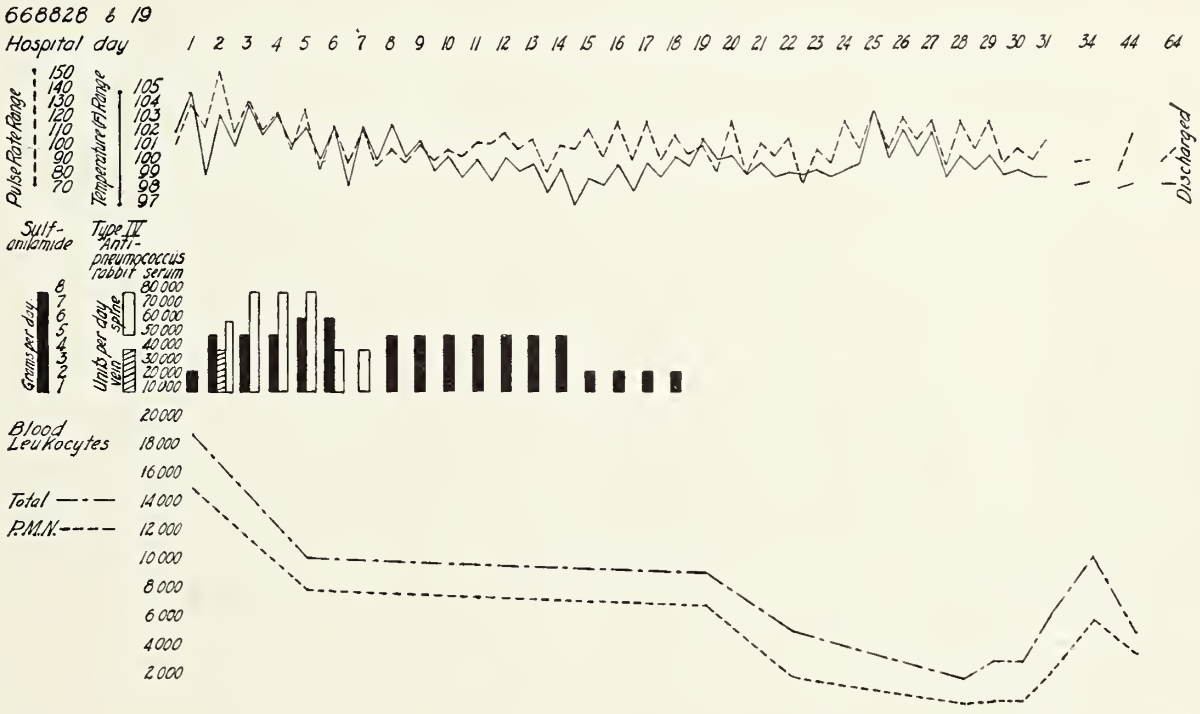

Fig. 1. Graph showing range of temperature and pulse, sulfanilamide and serum therapy, and blood leukocyte counts.

On May 19, the following neurological changes were noted: the pupils unequal with the left larger than the right, the right biceps reflex absent, and the left knee jerk diminished. Neck and back rigidity were still present but to a much less degree. The nystagmus had disappeared.

The patient required catheterization during the first twelve hospital days. On the twelfth and thirteenth days he was given pilocarpine, grains 1/10, four times daily. He had no difficulty in voiding after the first two doses of this drug. As soon as he became rational, at the beginning of the second week, it was noted that he had a profound bilateral nerve deafness. There was a total loss of hearing in the left ear and hearing for conversational voice in the right ear at one foot. The C512 tuning fork produced no sensation when placed on either mastoid process.

Progress of the illness otherwise seemed uneventful with gradual recession of the fever, disappearance of the neurological findings, and clinical improvement of the patient. On May 28, the nineteenth hospital day, a rise in temperature to 101.8 F. was noted. There were no unusual symptoms and the blood leukocyte count that day was 9500 with a normal differential. The fever rise was for that one day only, progressively declined the following days and on the twenty-second hospital day it was down to 99.4 F. However, the leukocyte count that day was 5250 with 40 per cent neutrophiles, 48 per cent lymphocytes, and 12 per cent basophiles. A malignant leukopenia (agranulocytosis) was more definitely shown in the leukocyte and differ-

ential counts on the twenty-eighth day. No treatment was instituted for the agranulocytosis from which the patient made a spontaneous recovery by the thirty-fourth day when the leukocyte and differential counts were nearly normal. Detailed blood studies are shown in Table II.

An added complication appeared on the twenty-fifth hospital day when there was a sharp rise in temperature to 103.6 F. with evidence of pharyngitis, cervical adenitis, and left otitis media. A left myringotomy was performed and staphylococcus albus was cultured from the pus obtained from the middle ear. Recovery from this infection was prompt, the patient's temperature on the thirty-fourth hospital day was normal and remained so throughout the remainder of his total hospital stay of sixty-four days.

On June 20, when he first attempted to walk, his sense of equilibrium was found to be almost entirely lost. Caloric tests showed no response from either labyrinth. This, together with the deafness, indicated practically a complete destruction of both eighth cranial nerves. When he left the hospital on July 12 he had learned to walk fairly well by watching his gait carefully but he was still almost totally deaf. Otherwise he had made a full recovery from his illness.

The patient has been seen several times since then, the last time on December 7, 1938. Audiograms then showed slight increase in hearing acuity by air conduction for low tones in the right ear but still a total loss in the left ear. Bone conduction showed only a minimal residual for low tones in both ears. He had learned to compensate for the ataxia by vision and had acquired some skill in lip reading. Except for the only neurological sequela of the bilateral eighth cranial nerve involvement he was in excellent health.

Comment

Since both sulfanilamide and specific serum were used in this case the efficacy of either one alone could not be determined. Spinal drainages were done daily just preceding each intraspinal serum injection and for four days after serum was discontinued. The drainages were likely a helpful therapeutic adjunct but no more than that. Eradicating a focus of pneumococcic infection, had there been one present, would have been of more value. The total amount of serum given was about twice that which is now considered sufficient; at the time this patient was treated there was no established therapeutic limit. The agranulocytosis was due to toxicity or idiosyncrasy to sulfanilamide, since the patient had nausea and vomiting when the blood level of the drug was only 5.3 mgm. per cent and had a secondary rise in temperature four days before the white blood cell changes were noted. Although the patient was catheterized twenty-five times the urine was regularly negative, probably due to the antiseptic action of the sulfanilamide. Deafness is often a sequela of meningitis but the added involvement of the vestibular branch of both eighth cranial nerves is very unusual.

Summary

1. A bacteriologically proven case of pneumococcic meningitis with recovery is reported.

2. The case was complicated by agranulocytosis and otitis media and had the unusual residual of complete bilateral eighth cranial nerve involvement.

3. Treatment was with sulfanilamide, specific antipneumococcus rabbit serum, and repeated spinal drainage.

IDIOPATHIC BENIGN HYPERTROPHIC PYLORIC STENOSIS IN THE ADULT

FRANCIS E. KIBLER, M.D.
Austin, Minnesota

IN 1788, H. Beardsley of Connecticut recognized pyloric hypertrophy at an autopsy performed on a five-year-old girl.

Hypertrophic pyloric stenosis in adults was first recognized in 1835 by Jean Cruveilhier, who described and illustrated this condition in a volume of "Pathological Anatomy of the Human Body" published in Paris. His treatise was complemented by the presentation of two personally treated cases. J. Boas in 1898, reported two cases of hypertrophy of the pyloric muscle which had been positively diagnosed clinically and later confirmed at the operating table. He believed that the hypertrophy was secondary to inflammation and argued for "stenosing gastritis" as the etiological factor.

Incidence

Pyloric stenosis in the adult has been generally conceded to be quite uncommon. However, according to several writers, this condition is of much more frequent occurrence than is ordinarily believed. According to R. Rossle,[21] specific examination in over 5,000 autopsies performed in Berlin and Basle, revealed that 3 per cent of adults were so afflicted, even with the extreme forms, and that from past histories, very few were known to have had associated symptoms during life. The discrepancy between the incidence and the clinical recognition of the disease is probably explained on the basis of a failure to recognize the symptoms per se, or to confuse them with the symptoms of a concomitant chronic gastritis, ulcer or biliary disease.

The manifestations of this lesion appear most commonly between the ages of twenty and forty, and occur more frequently in females than in males in a ratio of about one and one-half to one, and are observed more frequently in members of the Latin race rather than in the Anglo-Saxon. All authors agree, however, that an inherited predisposition is necessary for the development of this disease.

Etiology

In reviewing the literature for the etiological concepts of this condition one is depressed by the multiplicity of the theories and staunch arguments presented for each, as to whether the hypertrophy is primary in the muscularis with secondary changes in the mucosa and submucosa, or vice versa; or whether the adult form is simply a carry-over of the infantile condition with late manifestations, or a separate and distinct lesion developing in adult life.

Morton[18] and Deaver[7] believe that a type of obstruction similar in all respects to the congenital form may arise from spasm of the pylorus. Conversely A. James Walton[26] maintains that the presence of great muscular hypertrophy indicates the presence of a congenital pyloric stenosis, in that evidence is lacking that hypertrophy will follow pylorospasm.

McClure,[16] in reporting five cases pathologically similar to congenital pyloric stenosis, but occurring in adults, states that: "It is probable that these are all mild examples of the congenital disease, in which the obstruction has been overcome by hypertrophy of the gastric muscle and it is only later in life that compensation fails and symptoms become manifest."

Bassler[3] states that chronic alcoholism is a prominent factor in most cases, and that hypertrophic gastritis, with a subchlorhydric, achlorhydric or achylic condition, is always present and may be the primary factor.

Donati[8] maintains that both congenital and acquired factors, especially those relating to the production of pyloric spasm, are involved in the pathogenesis.

H. Knauer[14] very aptly writes that two different terms for the same or at least extremely similar disease entities indicate that the etiology has not been completely explained. Some apply the term hypertrophic pylorostenosis, assuming an abnormal narrowness of the mucosa (primary stenosis) followed by a secondary muscular hypertrophy, others adhering to pylorospasm as producing a "primary" tumor-like muscular hypertrophy. He believes that the various factors concur to produce what he designated as "pylorospasm in simultaneous hypertrophic pylorostenosis."

McNamee[17] suggests the term "idiopathic pyloric stenosis," to which the writer would include benign hypertrophic, thus giving a term that is descriptive from both the pathological and clinical aspects, and at the same time non-controversial from the etiologic viewpoint.

Lerck-Hanssen,[17] of Finland, concludes that the hypertrophy is the result of a chronic gastritis and prepyloric ulcer since one or both were always present in his cases of hypertrophic stenosis. These findings have been repeatedly borne out by American, German, English and French pathologists. Because of these associated antral and prepyloric inflammatory changes, the evidence favors the opinion that inflammation (chronic hypertrophic gastritis) is the most important single factor in the production of benign hypertrophy of the pylorus, relegating the congenital theory to a secondary position. Quoting Ross Golden[10]: "However, the foundation for the development of hypertrophic changes under proper stimuli must be considered from the viewpoint of a 'congenital predisposition.' "

In conclusion, the various theories may be summarized in the order of their respective merits:

1. Mixed theory: dependent upon two or more of the above mentioned concepts.
2. Congenital predisposition: latent in character and manifesting itself on activation by nervous stress and strain, or inflammation (local or general), or progressive debility and the like.
3. Acquired: secondary to ulcer, gastritis, syphilis or tuberculosis, local evidences of which have disappeared.
4. Carry-over or continuation of the congenital stenosis of infancy.
5. Hypertrophying pylorospasm: dependent upon a prolonged hyperirritability of the parasympathetic nervous system with concomitant compensatory changes in the stomach, symptoms becoming increasingly manifest as compensation fails due to disruption of the viscero-visceral reflex of the component branches of the autonomic nervous system.
6. Neoplastic: the hypertrophy in reality a benign growth-myoma or fibromyoma.

Pathology

Cunha,[6] using the term idiopathic benign hypertrophic pyloritis, maintains that the condition is not a simple acute or chronic inflammatory gastritis with the associated mucosal changes usually found, but rather a distinct clinical entity with a characteristic pattern limited to the pylorus, the most outstanding feature being a hypertrophy of the mucosa and submucosa with secondary edema and hypertrophy of the muscularis. The intense thickening of the mucosal layer with concomitant enlargement of the folds causes obstruction by encroaching on the pyloric canal. Secondary changes, including stasis, may be moderate or extreme. At autopsy, the true nature of the lesion is frequently modified, due to rapid diminution of the edema following death.

According to Savarese,[22] the condition is "a special alteration of the pylorus characterized by a thickening of this portion of the stomach due to hypertrophy of the muscular tunic and without participation of the other layers." Thus by definition, the muscular hypertrophy is sharply distinguished from pyloric hypertrophy due to lesions primarily of different anatomical substrates, such as: simple inflammation, lues, tuberculous and neoplastic growths and peptic ulcers of the mucosa and submucosa.

Eustermann and Balfour[9] define true pyloric hypertrophy as: "an enlargement or overgrowth of the pyloric muscle, without an apparent causative or associated lesion." They are convinced that primary muscular hypertrophy with the anatomical changes simulating the infantile type is uncommon, whereas the adult form is associated most frequently with duodenal, gastric or cholecystic disease, such as: peptic ulcer, gastritis and chronic cholecystitis.

Gross examination reveals a smooth circular or fusiform swelling completely encircling the pylorus. The consistency of the tumefaction varies from that of normal liver to the non-resilient firmness of cartilage. The tumor is usually sharply demarcated, but this is dependent upon the degree of associated secondary thickening and dilatation of the stomach wall. However, the duodenal extremity is always sharply differentiated, since the obstruction is at the proximal extremity. The tumor is freely movable through the normal range of pyloric mobility in the absence of a primary or secondary peri- or para-duodenal lesion. Fixation of any degree would immediately indicate underlying pathology of either the stomach, duodenum, gallbladder or pancreas. The cut surface reveals a variable thickening of the pyloric wall, chiefly of the muscular tunic, which is pale red in color and of a more fibrous consistency than normal muscle. The mucosa and submucosa strata are likewise thickened and edematous. The lesion specifically involves the entire length of the pyloric canal and is sharply confined to its borders, the caliber of the canal being determined largely by the degree of the hypertrophy of the circular (inner) muscular layer, while complete obstruction is dependent upon prolapse of the edematous or hypertrophic prepyloric gastric mucosa, or simple edema with or without hypertrophy of the pyloric mucosa itself.

Microscopic examination is essentially that of simple hypertrophy of the circular layer of the muscular tunic and to a less extent of the mucosa and submucosa. The muscle cells are of normal form and arrangement but increased in size—a true hypertrophy. No changes are present in the connective tissue stroma, serous or subserous layers. Occasionally there may be found a lymphocytic infiltration of the mucosa, which at times extends into the muscularis mucosa and submucosa.

According to Judd and Thompson,[12] hyperplasia is also associated with the hypertrophy, and occasionally hyperplasia, atrophy or inflammation of the other layers of the pylorus is present, including the peritoneal covering. Savarese[22] firmly believes that it is impossible, by both gross and microscopic examination, to differentiate between a true muscular hypertrophic stenosis and a pyloric hypertrophy associated with inflammatory changes, quoting: "distinction is dependent upon causal and evolutive differences of a process which is essentially the same in every case."

Symptoms

The symptoms of idiopathic benign hypertrophic pyloric stenosis are from early life multiple and variable, vague in character, with exacerbations precipitated by any intercurrent infection, patients obtaining at best only temporary relief from antispasmodics and various diets. As a result they wander from one doctor or clinic to another in search of aid, in the course of which they are subjected to many x-ray studies and other laboratory procedures, each doctor expecting to find an ulcer or neoplasm. In absence of either of these they are informed that they have "nervous indigestion" and earmarked as neurotic. However, with the onset of mechanical obstruction, a group of symptoms predominate the picture and mask those of the underlying cause or causes. Thus the true nature of the obstruction can be learned only by thorough investigation of the past history. Even then the internist and surgeon are very frequently baffled, not only as to etiology, but with regards to the diagnosis itself.

The usual clinical course is a syndrome of chronic intermittent, progressive, and finally continuous gastric dyspepsia occurring most frequently in young asthenic adults of the so-called high-tension type. Early, the symptoms may vary from time to time so as to mislead the clinician. Chronic pylorospasm is a frequent diagnosis, explained on basis of reflex irritation from a "chronic appendix," gallbladder, or colitis. In these cases an appendectomy gives only temporary, if any, alleviation of symptoms. Duodenal ulcer or duodenitis may be simulated, in that pain and discomfort appear within a few hours of eating, and in not a few, relief is obtained by ingestion of food, alkalies, or by vomiting.

As the obstruction manifests itself, the periodicity is lost and the attacks are longer and finally merge one into the other. In the primary or idiopathic form, the symptoms are of long duration, frequently traced back to childhood and characterized by remissions and exacerbations; whereas, in the presence of a stenosing ulcer the intervals of relief, though not as long as in the idiopathic form, will be much more prolonged than that in carcinomatous obstruction.

Pain.—The subjective symptom of pain is due partly to the mechanical obstruction itself and partly to the associated secondary gastritis, with the result that the pain is continuous with exacerbations from ingestion of food or water. As the stomach dilates, losing its normal tubular form, the pain appears immediately after ingestion of food instead of after an interval as in pyloric ulcer. The pain at first is not severe, but is more a sensation of fulness and discomfort which steadily increases with time and as the stomach capacity increases. In addition to the constant dull aching pain, due to dilatation, there are waves of a more severe crampy nature, due apparently to peristaltic action.

Vomiting.—The truly characteristic vomiting is that of large quantities at long intervals. The longer the condition has existed the more tolerant the stomach becomes of its contents and the greater the retention before emesis appears.

Hematemesis and Melena.—In the presence of idiopathic muscular hypertrophy, fibrosing ulcers, and scirrhous neoplasms, loss of blood is unusual, although small quantities may be discovered by chemical analysis. However, with fungating growths, brisk hemorrhages may occur from time to time.

Appetite.—Anoxeria due to gastritis is the rule. However, in the early stages, the relief from distress when the stomach has been emptied, produces a desire for food. Thus one must remember that a good appetite does not exclude the possibility of pyloric obstruction.

Loss of Weight.—Wasting is nearly always present, partly on the basis of the secondary gastritis and partly due to the fact that so little food ever reaches the intestine for digestion and absorption. As a result, the physiology of the large and small bowel is upset and constipation of a severe grade is a prominent complaint.

Physical Examination

Evident wasting is present in all patients, the degree of which is dependent upon the length of time that the obstruction has existed. Sometimes the cachexia is more marked in the benign than in the malignant type of stenosis.

The lower abdomen is retracted while the epigastrium is full from the presence of a distended stomach.

Tenderness to deep palpation, with or without a wide area of hyperesthesia over the epigastrium and left half of abdomen is generally present. A succussion splash may be elicited over the distended stomach, provided the hypertrophy of the gastric wall is not excessive, and simple percussion permits fairly accurate outline of the viscus. Occasionally a hypertonic stomach is present and the contracted organ is palpable. In the presence of marked gastric hypertrophy, peristaltic waves may be seen moving from left to right and are accompanied with complaints of pain, followed by emesis of small amounts of mucus and the normal yellowish watery gastric secretion when food has not been taken. Percussing or palpating the abdomen, or having the patient drink a small amount of water will precipitate peristaltic action. Sometimes (variously reported to occur in from 50 to 75 per cent of the cases) a definite tumor may be felt in the region of the pylorus. If benign in nature, the mass is somewhat rounded, firm but not hard, movable and smooth in outline; whereas, a malignant growth is hard, irregular, fixed and less well defined. Confirmatory evidence of the latter may frequently be found by palpation of metastatic growths along the liver border or in the pelvic cul-de-sac.

Pathognomonic symptoms of pyloric obstruction are:

1. Visible peristalsis
2. Pain followed by projectile vomiting.
3. Evidence of retained and fermented food
4. Succussion splash
5. Palpable tumor mass
6. Absence of blood in vomitus and stool
7. Absence of bile in vomitus

Diagnosis and Differential Diagnosis

The diagnosis of idiopathic benign hypertrophic pyloric stenosis may be relatively easy, but in the majority of instances, the diagnostic acumen of the clinician and surgeon are sorely taxed. According to Toupet and Mouchet,[23] this is impossible even in the operating room. They maintain: "that whatever the clinical picture may be or whatever the appearance of the condition at operation, it is impossible to eliminate the possibility of cancerous infiltration until microscopic examination is made."

A history of long-standing vague gastric dyspepsia, progressive in nature, and characterized by a progressive syndrome of episodic pain, vomiting, retching, loss of weight and constipation, in which the remissions become less frequent and of shorter duration, with each exacerbation becoming more intense and prolonged, should suggest the possibility of this condition.

The differential diagnosis is at all times difficult and not infrequently impossible. However, a careful history and thorough physical examination complemented with adequate laboratory procedures, will in most cases allow the clinician to reach a definite diagnosis.

The most commonly confounded conditions are:

1. *Gastric and Duodenal Ulcer.*—Any chronic ulcer near the pylorus tends toward stenosis. Usually the ulcer is of long standing and thus the patients are frequently past fifty years of age. The actual narrowing is due to a dense fibrosis spreading from the ulcer and surrounding the canal. In others, a penetrating ulcer that becomes adherent to the gallbladder, liver or pancreas, may, by the associated inflammatory reaction and edema, help in narrowing the lumen. Adhesions following this type of condition may, on contraction, draw upwards and kink the pylorus. The stomach usually shows a secondary hypertrophy and dilatation, and gastritis is usual from the concomitant stagnation.

2. *Pyloric Spasm and Simple Fibrosis.*—Pyloric spasm secondary to, and associated with, disturbed physiology or actual pathological changes in the gallbladder, appendix, colon and kidneys, is well known and demonstrable through x-ray and fluoroscopic examination. Walton[27] and Oliver[19] seriously doubt that pylorospasm is capable of producing hypertrophy of either the pylorus or of the gastric wall; such changes should be regarded as definite evidence of an organic lesion in the pylorus. McClure[16] suggests the use of atropine sulphate hypodermically to rule out pylorospasm. Under the fluoroscope the effects of relaxation of the hypertonic muscle is readily visible, and if hypertrophy of the muscle is actual, complete disappearance of the constriction will not occur.

Simple primary fibrosis of the pylorus is a doubtful entity. Most investigators are of the opinion that an ulcer or gastritis is the primary lesion.

3. *Gastric Tumors.*—Any neoplasm at or near the pylorus may lead to obstruction by infiltration of the walls with or without projection into the lumen. Scirrhous carcinoma and a reactive fibrosis may cause a narrowing of the canal identical to that scarring resulting from a gastric ulcer. Usually, however, this thickening and narrowing involves a greater area. A polypoid growth may cause an intermittent type of obstruction through a ball-valve mechanism. Complete obstruction has been reported, wherein the tumor was drawn through the pyloric ring, resulting in an intussusception of the stomach.

4. *Paragastric and Paraduodenal Inflammation.*—Chronic inflammatory changes about the pylorus may result in a secondary constriction. The commonest causes of this phenomenon are cholecystitis and pancreatitis.

5. *Paragastric Carcinoma.*—Carcinoma of the gallbladder, hepatic or transverse portions of the colon, and head of the pancreas may narrow and obstruct the pylorus by compression, actual infiltration, or as the result of the inflammatory reaction.

6. *Kinking of the Pylorus and Duodenum.*—Temporary acute obstruction due to kinking is most common in the presence of a ptotic and mobile stomach. Similarly a ptotic and mobile kidney may draw the duodenum downwards and cause kinking and obstruction, giving rise to one of the varieties of Dietl's crisis. The obstruction generally being acute and temporary in nature, is not followed by hypertrophy of the stomach walls and visible peristalsis. The symptoms occur when the patient is upright and are relieved almost immediately, or, at least, ameliorated by reclining.

7. *Unusual conditions* that have been reported are merely listed:

(a) Duodenal compression by the superior mesenteric or middle colic arteries in the presence of an exceedingly short mesocolon. Symptoms are present when colon is full.

(b) Congenital bands—the so-called "primary periduodenal adhesions."

(c) Calcified retroperitoneal lymph nodes.

Chronic duodenal obstructions do not produce muscular hypertrophy of the pylorus. Symptoms of an aching epigastric distress with nausea and occasionally emesis, occurring soon after eating and exaggerated by standing or sitting, and relieved by lying prone are pathognomonic of duodenal obstruction. Fluoroscopic examination reveals a dilated duodenum with stasis, exaggerated peristalsis and antiperistalsis. In all cases, regurgitation of the barium into the stomach through a patent pylorus immediately rules out the presence of a pyloric lesion.

Laboratory Procedures

Urinalysis.—There may be a high specific gravity resulting from dehydration.

Blood.—In the presence of a dehydration the hemoglobin, red and white blood cell counts are elevated. A leukocytosis would be, of course, only relative, and the differential count normal in the absence of a coexisting infection. However, an actual leukocytosis is present in severe dehydration.

Sedimentation Rate.—This is not increased.

Blood Wassermann.—The test should be made to rule out neuro- and viscero-syphilis.

Gastric Analysis.—Free hydrochloric acid may be diminished or absent due to the associated gastritis. Free acid will more likely be absent if the obstruction is malignant. Total acidity is increased owing to retention fermentation. Bile salts and blood are absent in the benign type of obstruction. Fractional analysis will show an increase of total acid and retention of starch in all specimens.

Roentgenologic Examination.—The fluoroscopic examination is the most important single procedure in the diagnosis of pyloric obstruction next to the taking of a detailed history. "Spot" roentgenograms are useful for a permanent record of the case. Routine gastric x-rays as taken by the technician are useless.

Numerous "signs" have been discovered and pronounced by their authors to be pathognomonic for idiopathic benign hypertrophic pyloric stenosis. However, these have not been infallible in many cases, even in the hands of their particular exponents; but nevertheless they have aided in advancing roentgenologic diagnosis of diseases of the stomach and duodenum.

Typical findings show varying degrees of pyloric obstruction with dilatation of the stomach, strong and frequent peristaltic waves, and retention of the motor meal. Peristalsis will appear at varying intervals and may result in esophageal regurgitation.

It is generally conceded that a concentric pyloric defect with an elongated narrow canal and intact mucosal relief establishes the diagnosis.

Golden[10] believes that the demonstration of mucosal folds in the involved area is the most important differential point from the roentgenologist's viewpoint. Hypertrophic changes in the mucosa, even in the presence of marked muscle hypertrophy, are easily discernible, whereas carcinomatous infiltration obliterates these folds. In some cases only one wall may be infiltrated and thus cause confusion. Regressive obliteration of the folds may again serve to cloud the issue.

According to Kirklin and Harris[13]: "Concentric indentation of the bulbar base in conjunction with prepyloric narrowing is pathognomonic of pyloric hypertrophy." The base of the normal bulb is flat; the concavity or indentation is believed to be produced by a partial invagination of the hypertrophied muscle into the bulb.

The presence of a patent pylorus indicates a duodenal obstruction. A long irregular canal, with or without filling defects, suggests carcinoma. A well defined defect, niche, or crater indicates ulcer. Very frequently the barium is unable to pass the pyloric ring and enter the canal, and although an obstruction to the stomach outlet is thus evident, the true nature cannot be determined. When this is present, as mentioned previously, atropine administered by injection is invaluable in differentiating between pylorospasm and an organic lesion, as the cause of the obstruction.

Treatment

In the light of our present-day concepts regarding the true cause and nature of the disease, and the reasonable doubt necessarily associated with the clinical diagnosis thereof, surgery offers the only hope for cure.

Bennett[5] maintains that medical treatment of pyloric stenosis fails in the majority of cases because it fails to meet the requirements and habits of the individual patient. Quoting: "There is no other disease in which the personal factor is of more importance. It is a mistake to assume that organic narrowing of the pyloric canal, even of high degree, must in all cases be treated surgically." The principal gastric function is to secure liquefaction of food; by which is not meant solution, but a chyme with the consistency of a weak gruel. Therefore, food requiring prolonged gastric digestion must be avoided and a diet with the consistency of chyme substituted. Bennett feels that a regimen as outlined below, plus indicated medicines pushed to the point of saturation or tolerance of each individual patient so as to secure gastric rest, will promote permanent healing and return of health. He advises: gastric lavage in the presence of emesis, dextrose lemonade for from one to two days, followed by diluted milky foods and progressing to a semi-fluid diet for several weeks.

The surgical treatment is undertaken for the purpose of: (1) establishing a definite diagnosis; (2) relieving permanently the obstruction by the simplest, yet adequate, method deemed advisable for that particular case; (3) reëstablishing the normal motor and secretory functions of the gastrointestinal tract.

Preoperative and postoperative treatment is of paramount importance, the fundamentals of which are well known. The details alone vary, and are dependent upon the individual surgeon's pet ideas. However, with regards to anesthesia, ether is still considered by the majority of surgeons to be the best and safest anesthetic, and that it should be administered by the open drop method.

In 1912 Rammstedt introduced his well-known operation, which consisted of incising the serosa and muscularis down to the mucosa and spreading to allow the mucosa to gape through the hernia. Since then several modifications have been introduced. Early surgeons performed gastroenterostomy almost exclusively, but since 1912 a pyloroplasty of some form has been the preferred procedure.

The operations that the various surgeons consulted have used in the treatment of this condition are listed below:

1. Pylorodiosis—by Loreta's technic (dilatation through gastrotomy wound) or Hahn's method through the unopened stomach.
2. Pylorodiosis by the Rammstedt technic and its modifications.
3. Nicol pyloroplasty with or without gastrotomy.
4. Finney's operation—lateral or pyloric gastro-duodenostomy.
5. Heineke-Mikulicz pyloroplasty.
6. Hemi-resection of anterior portion of pylorus.
7. Posterior gastroenterostomy.
8. Resection of pylorus followed by Polya or Billroth II anastomosis.
9. Gastropylorectomy.

The last two procedures are advocated by the continental surgeons, who base their choice of operation on the claims that only the microscopic examination can rule out the presence of malignancy, and therefore, any procedure that does not allow for this possibility is inadequate.

However, the Rammstedt pylorodiosis and the simpler pyloroplastic technics have stood the test of time and have shown just as great a percentage of cures and certainly a much lower morbidity and mortality rate than have the more extensive procedures. However, the operative results of the Rammstedt operation can be satisfactory only if the entire circular muscle is divided, wide separation and retraction of the divided muscle being entirely of secondary importance. Timely operative interference remains, none the less, the most important prerequisite.

Case Report

A white female, thirty-six years of age, was seen complaining of abdominal distress of eighteen years' duration.

Following an operation for strangulated incisional hernia in 1920, the patient has suffered from episodes of gaseous distention, pyrosis, nausea and abdominal distention lasting from three to four days and occurring at intervals of from four to six weeks, at first relieved by gastric lavage or vomiting.

For the past nine years the symptoms have gradually progressed, with remissions of shorter duration so that at present these "spells" occur every ten to fourteen days, with emesis and pain the predominant symptoms. The pain in the epigastrium radiates to the left side and back and vomitus at first contains undigested food and later only mucus and yellow fluid. During the height of the attack the pain and retching are simultaneous and occur without preceding nausea. Bile or blood had never been observed in the vomitus.

She complains of hunger and thirst but has been afraid to eat for fear of precipitating pain and emesis. During this time the patient has been under the care of one clinic and had undergone many and varied examinations. A diagnosis of pyonephrosis was made in May, 1936, and was followed by a right nephrectomy.

Following this she was entirely free of symptoms for about six months, then they recurred in more severe form. At this time she underwent another operation to relieve a "twisted intestine." However, the postoperative course was complicated by epigastric distention, pain and vomiting. Following her discharge from the hospital, examinations failed to locate any cause for her symptoms, and she was finally told that she was "neurotic" and referred to a neurologist and discharged.

The patient was first seen in June, 1938, complaining of pain, vomiting and abdominal distention recurring at intervals of from two to six days. Associated with these symptoms were complaints of frequency, burning pain on urination, nocturia and left lumbar pain.

Examination revealed a well developed but undernourished emotionally unstable adult white female. Gaseous eructations were frequent during the examination. Her face and neck were flushed; the tongue, lips and skin dry. The abdomen was full but not tensely distended; there were no palpable masses, visceræ or herniæ noted. Peristaltic waves were not observed and there was no free fluid demonstrable in the abdomen. Borborygmi were present over the entire abdomen, more pronounced in the right lower quadrant. Tenderness was elicited on palpation of the upper half of the low midline scar, and also on light Murphy percussion of the left flank. There were healed lower midline, right mid-transrectus and right lumbar incisional scars.

The patient's temperature was 99°, pulse 88, blood pressure 160/100. Urinalysis was normal save for an occasional red blood cell.

The tentative diagnoses were: (1) chronic high intestinal obstruction; (2) essential hypertension; (3) possible left upper urinary tract lesion.

In view of her past history, a urologic study was deemed advisable before considering abdominal section. Cystoscopic examination followed by retrograde pyelography (left), excretion urography, and renal function tests were negative except for absence of the right kidney. However, the x-ray films showed several loops of ileum and stomach distended with gas.

The following day the patient felt considerably improved and asked to be released for a few days before submitting to operation. She was readmitted to the hospital on July 10, 1938, acutely ill and complaining of constipation, abdominal pain and distention, repeated emesis and retching, of twelve hours' duration. Her temperature at this time was 98°, pulse 100, blood pressure 122/84, urinalysis negative and white blood count 11,650.

Continuous gastric siphonage was instituted and parenteral fluids administered. Retching continued, finally becoming almost continuous after a period of six hours, in spite of siphonage. At this time visible peristaltic waves were observed in the epigastrium, traveling from left to right. The entire abdomen was tympanitic to percussion, generally tender, but more so over the upper half. No masses were palpable. Borborygmi were general over the entire abdomen, and a high-pitched whistling sound was heard just below and to the left of the umbilicus.

Flatus was passed occasionally and colon flushing only added to the patient's distress. The temperature rose to 100° and pulse rate gradually increased.

A diagnosis of acute and chronic intestinal obstruction with associated duodenal obstruction was followed by an exploratory laparotomy. The abdomen was opened through the old right transrectus scar, and exploration revealed an incomplete obstruction of the ileum about five feet above the ileo-cecal juncture, due to an incarcerated Richter's hernia at the upper angle of the old midline incisional scar. This was reduced and the hernia repaired by the intra-abdominal approach, and the intestinal pouch invaginated. The stomach was distended with gas, the walls thickened and edematous, and the pylorus completely obstructed by a typical circulaur muscle hypertrophy. This was relieved by the Rammstedt method and the incision covered by the transverse approximation of the serosa. The small bowel distention, in the meantime, had decreased considerably and flatus and liquid stool was escaping from the rectal tube.

The postoperative course was extremely uneventful. Oral fluids were taken as soon as the patient recovered from the anesthetic, and food was allowed the following morning. The patient was discharged, as improved, on the twelfth postoperative day. Subsequent office examinations have confirmed complete recovery. In a letter received in December, 1938, the patient states that for the first time in nine years she has been completely free of abdominal distress and is able to eat any and all varieties of food with impunity.

This case has been presented since it rather fully reiterates the points previously reviewed. In addition, the associated Richter's hernia and partial intestinal obstruction added to the confusion of an already difficult diagnostic problem. The question of x-ray investigation of the stomach and duodenum has no doubt already been raised. This examination had been performed, and found negative, by a competent radiologist within a period of three months prior to her first visit at this clinic; and in addition, such an examination was impossible at the time of her second admission, due to the almost continuous vomiting, even in the presence of an automatic gastric suction apparatus.

PSORIASIS*

A Clinical and Laboratory Statistical Study

JOHN F. MADDEN, M.D.
Saint Paul, Minnesota

PSORIASIS is one of the more common skin diseases. However, very little is known about it except its clinical appearance and histopathology. This statistical study helps to evaluate certain allegations regarding psoriasis and shows some facts concerning the disease. There were forty-four cases examined. Of this number twenty-eight were females and sixteen males. The average age was thirty-six years. The youngest patient was four years of age and the oldest eighty-two.

Onset and Duration.—The average age at onset was twenty-six years. The disease does not seem to appear at any definite time of the year. The onset was in the fall in nine cases, in the winter in nine, in the spring in eight, in the summer in thirteen, and five patients did not remember when the disease began. Psoriasis had been present for fifty-three years in one case and only three months in one instance. The average duration was twelve years.

Remissions and Seasonal Variations.—In thirty-two cases, 73 per cent, the patients were never entirely free from psoriasis. Complete single remissions occurred in six cases during the summer when the patients took frequent sun baths. One patient did not have any lesions for four years, and two for one year. Pregnancy, rheumatic fever, and arsenic pills were given as the cause of remissions in single cases. No seasonal variation was noticed by twenty-one patients, twenty-two patients thought that the disease was better during the summer, and one patient stated that the eruption improved during the winter. Most of the cases went through cycles of remissions and exacerbations of varying lengths.

Types of Lesions and Regions Involved.—Various sized circinate and gyrate patches were found in thirty cases, small punctate or guttate papules were found in twenty cases, and large infiltrated plaques were observed in eleven cases. In some patients only one type of lesion was present, but in most cases several types were noted. The scalp was involved in thirty-five patients, the arms in thirty-two, the trunk in thirty, the legs in thirty, the face in twenty-one, the dorsum of the hands in thirteen, the external genitalia in ten, the nails in eight, the gluteal cleft and perianal region in four, and the palms and soles in one case. The appearance of lesions on the face in 48 per cent of this series seems high because one usually thinks of psoriasis occurring on the covered portions of the body. The scalp was attacked with greater frequency, 79 per cent, than any other location.

---

*From the Ancker Hospital, Saint Paul and the Division of Dermatology and Syphilology, University of Minnesota. Dr. H. E. Michelson, Director.

Symptoms.—Itching was severe in ten cases and moderate or slight in nineteen cases. The pruritus was most marked in those patients who had lesions in the scalp and was intensified during exacerbations when new papules appeared. Painful and bleeding fissures were noted in three cases. One patient complained of severe burning sensations in the palmar and plantar lesions. No subjective symptoms were present in eleven cases. All the patients were embarrassed by the disease. Most psoriatics would not wear bathing suits nor would they attend social gatherings if the eruption was present on the face. The women often wore long sleeved dresses the year round in order to hide the lesions. Psoriasis cannot be considered an asymptomatic disease when thirty-three patients, 75 per cent, in this series had definite disturbing symptoms and all suffered some mental anxiety because of the disease. These figures and most of the others throughout this clinical statistical study agreed with those of Lane and Crawford.[2]

Changes in Body Weight.—A gradual gain or no appreciable change in weight was noted by thirty-one patients. A loss of weight caused by diet or manual labor of 7 pounds in three weeks, 14 pounds in three months, 25 pounds in six months, 26 pounds in four months, 30 pounds in two years, and 50 pounds in one year caused no change in the eruption in six cases. While on a reduction diet two patients lost 35 and 50 pounds in six months and the eruption was reduced to a few scattered papules. New lesions appeared as soon as the patients abandoned the diet and began to gain weight. A gain in weight of 30 pounds in two years, 30 pounds in five years, 35 pounds in six months, 40 pounds in eighteen months, and 40 pounds in five years was accompanied by a marked increase in the psoriatic eruption in five patients. In the eight patients showing an abnormal loss of body weight no appreciable effect on the psoriasis was observed by six patients. While marked loss of weight had little effect on psoriasis an abnormal gain in weight seemed to make the disease much worse.

Intercurrent Diseases.—In thirty-one patients no intercurrent diseases except arthritis, rheumatic fever, or foci of infection were noted. These diseases will be considered later. Measles in two cases, pleurisy in two cases, and parotiditis, quinsy, pertussis, central nervous system syphilis, cholelithiasis, septic abortion, hypertrophied prostate with cystitis, lung abscess, and syphilitic hepatitis in single cases had no noticeable effect on the patients' psoriasis. The eruption became much worse during an attack of nephrolithiasis in one case and cholelithiasis in another. One patient stated that the disease almost disappeared while he was receiving therapeutic malaria for syphilis. The above intercurrent diseases had only a transitory effect on psoriasis in three patients and no effect on the remainder.

Pregnancy.—Pregnancy occurred thirty times in eight patients. No change was noted in the psoriasis during fifteen pregnancies. In fourteen pregnancies the psoriasis almost disappeared. One patient stated that the first lesions recurred on the nipples after she had been nursing her baby for about five months. The lesions usually began to disappear at the end of the first trimester and the disease steadily improved during the remaining months of pregnancy. If a patient's psoriasis improved or showed no change during her first pregnancy a similar experience was observed in succeeding pregnancies.

Arthritis.—Arthritis appeared at some time during the presence of psoriasis in eleven cases (25 per cent). Arthritis did not immediately precede, accompany, or follow psoriasis in any case. Acute arthritis with fever which lasted three or four weeks in five cases, chronic arthritis of two to fifteen years duration in four cases, and acute arthritis with fever followed by chronic arthritis in a single case had no noticeable effect on the eruption. One patient with chronic arthritis and psoriasis stated that both diseases had exacerbations and remissions simultaneously. Although arthritis was observed in 25 per cent of this group of psoriatics, ten of the eleven patients could not see any direct relationship between the signs or symptoms of either disease.

Menstruation.—Twenty patients in this group were subject to menstruation. No change in the psoriasis was seen during the menstrual period in thirteen cases. The lesions became more erythematous, the itching was more severe, or the scale was more noticeable three or four days before or during the menstrual period in seven cases. Menstruation temporarily aggravated the signs or symptoms of psoriasis in 35 per cent of this series.

Foci of Infection.—Definite foci of infection were discovered in twenty-three patients (52 per cent). Nine patients had abscessed teeth, eight had chronic tonsillitis, four had chronic prostatitis, four had cervicitis and cervical erosions, and three had chronic sinusitis. These foci of infection were removed or treated until the infection could no longer be detected, but there was no change noted in the psoriasis.

Familial Incidence.—The patients had ninety-one brothers and ninety-five sisters. Of this number six sisters had psoriasis, but these occurred in two families. One female patient's mother and two sisters had the disease while two brothers and four children were not affected. Another unmarried female patient's father and four sisters had psoriasis while three brothers and two sisters were free from the eruption. The rest of the parents did not have psoriasis. A paternal uncle and a maternal aunt and uncle had the eruption in two instances. As far as could be determined the grandparents were not affected. The children, thirty-eight girls and twenty-nine boys, did not have psoriasis. Psoriatic families were striking when found, but they were very rare in this group (only 4 per cent).

Previous Treatment.—Only two patients had not been treated before they were seen in our clinics. Most patients went from place to place receiving several of the therapeutic measures listed below while some became discouraged when the first agent did not cause prompt disappearance of the eruption. The following remedies were temporarily beneficial: ointments containing ammoniated mercury, sulphur, salicylic acid, or unknown ingredients in eighteen cases; arsenic compounds taken by mouth or given intramuscularly in ten cases; ultraviolet light in four cases; x-rays in three cases; proprietary medicine by mouth in two cases; sun baths in two cases; and ultraviolet light combined with tar ointment, frequent baths, scrubbing with green soap, milk injections, typhoid vaccine, proprietary ointment, Kettering hypertherm, and a reduction diet in single cases. The following remedies were of no benefit: ointments containing ammoniated mercury, sulphur, salicylic acid, or unknown ingredients in twenty cases; arsenic compounds given by mouth or intramuscularly in nine cases; autohemotherapy in four cases; ultraviolet light in two cases; and milk injections, proprietary ointment, proprietary medicine by mouth, x-rays, thyroid extract, and acriflavine injections in single cases. A tar salve and arsenic given by mouth were said to have been the cause of acute exfoliative dermatitis in single cases. In this group of psoriatics the above remedies were of no benefit or gave only temporary relief in the cases in which they were used.

Laboratory Statistical Study

Many laboratory tests were done on the patients to determine whether or not abnormalities existed.

Erythrocytes.—In forty patients the erythrocytes varied from 3,750,000 to 5,500,000 per cubic millimeter of blood. Only eight patients showed red corpuscles below 4,000,000 per cubic millimeter of blood.

Leukocytes.—The leukocytes ranged from 5,000 to 10,800 per cubic millimeter of blood in forty patients.

Differential Leukocyte Count.—The differential leukocyte count was normal in all forty patients.

Hemoglobin.—The hemoglobin was between 70 and 100 per cent in forty patients. Eight cases showed hemoglobins below 80 per cent.

Blood-platelets.—The blood-platelets varied from 150,000 to 380,000 per cubic millimeter of blood in twenty-one patients. They were under 175,000 per cubic millimeter of blood in three instances.

Bleeding Time.—The bleeding time varied

TABLE I

Number of cases	Degrees of free hydrochloric acid	Degrees of total acid
1	12	22
2	0	0

26	0	0
27	14	28
28	34	52

from one minute to three minutes 30 seconds in twenty-eight patients.

Coagulation Time.—Coagulation took place from one minute 30 seconds to six minutes in twenty-six cases. Two patients had coagulation times of eight and nine minutes.

Icterus Index.—The icterus index was from 4 to 12 in thirty patients. Only three had readings below 6.

Blood Calcium.—The calcium content of the blood serum varied between 8.3 and 13.2 milligrams for each 100 c.c. in twenty-nine patients. Two had below 9 and one over 11 milligrams of calcium for each 100 c.c. of blood-serum.

Urea-nitrogen.—The urea-nitrogen ranged from 13.3 to 21 milligrams per 100 c.c. of blood in twenty-seven instances.

Creatinin.—The creatinin varied from .88 to 1.6 milligrams per 100 c.c. of blood in twenty-six patients.

Gastric Contents.—The gastric contents were normal except the amounts of free hydrochloric acid and total acid. The normal figures for gastric acidity are from 25 to 50 degrees of free hydrochloric acid, and from 50 to 80 degrees of total acid. Table I shows the findings in twenty-eight cases.

Free hydrochloric acid was entirely absent or below normal limits in seventeen patients (61 per cent). Total acid was absent or below normal in eighteen (64 per cent). Ayres[1] found a low free hydrochloric acid and low total acid in 52 per cent of his patients. The degree of acid in the gastric secretion did not indicate how the psoriatics would respond on a low fat diet.

Urine.—Albumin, sugar, and casts were not found in specimens from thirty-nine patients. The urine of the patient who had the hypertrophied prostate gland and cystitis showed albumin, casts, and leukocytes.

Basal Metabolism.—The basal metabolic rate varied from minus 12 per cent to plus 16 per cent in twenty-three patients.

Widal Test.—The Widal test was negative in twenty-one cases.

Wassermann Test.—The blood Wassermann reaction was negative in forty-two patients and positive in the two known to have syphilis.

Sedimentation Rate.—The sedimentation rate of the red corpuscles during the first hour was 2 to 18 millimeters for fourteen females, 25 millimeters for one female, and 8, 5, 24, and 33 millimeters respectively for four males.

Mantoux Test.—The Mantoux tuberculin test was negative in fifteen patients and positive in one.

Blood Groups.—Fourteen patients were in group 4, thirteen in group 2, and three in group 3.

Blood Sugar.—The fasting blood sugar ranged from 78 to 130 milligrams per cent in twenty-five patients. Three patients, aged 62, 65, and 74, showed fasting blood sugars of 180, 182, and 160 milligrams per cent. These figures are high even in elderly individuals.

Uric Acid.—The blood of twenty patients (91 per cent of the cases) contained 2 to 4 milligrams per cent of uric acid. The blood of two patients showed 6 and 8 milligrams per cent. The observations of LeCoultre[3] that all psoriatics showed an abnormal increase in the uric acid in the blood could not be substantiated.

Summary and Conclusions

1. Psoriasis does not seem to appear at any definite season of the year.

2. Complete remissions are very rare. The disease is cyclic and the patients usually are better during the summer.

3. Itching is a common and distressing symptom in psoriasis. In this series 75 per cent of the patients had disturbing symptoms.

4. Marked loss of body weight had little effect on psoriasis, but an abnormal gain in weight seemed to make the disease much worse.

5. Intercurrent diseases have transitory or no effect on psoriasis.

6. Pregnancy had no effect or only temporarily benefited psoriasis.

7. There was no direct relationship between psoriasis and arthritis in this series.

8. Menstruation temporarily aggravated the signs and symptoms of psoriasis in 35 per cent of this series.

9. The removal or treatment of foci of infection had no noticeable effect on psoriasis.

10. The existence of psoriatic families was striking, but their occurrence was very rare in this roup.

11. Treatment which was of benefit in about half of the cases was of no benefit in a like number.

12. Many laboratory tests were done. The gastric contents showed the only abnormality. Free hydrochloric acid was entirely absent or below normal limits in seventeen patients (61 per cent). Total acid was absent or below normal in eighteen (64 per cent).

FURTHER STUDIES IN THE USE OF QUINIDINE IN THE TREATMENT OF CARDIAC IRREGULARITIES*

S. A. WEISMAN, M.D.
Minneapolis, Minnesota

IN 1936 I presented a report on a five-year follow-up study on the ambulatory treatment of auricular fibrillation with quinidine.[3] In discussing the treatment it was pointed out that, in order to get the most effective results, quinidine should be given in small doses to start with, slowly increasing the amounts daily, and that these small amounts should be given at frequent intervals. By this method the patient is more apt to establish a tolerance for quinidine and also to avoid the toxic effects that are so often attributed to its use. Since that time I have been engaged in the study of the excretion time of quinidine from the blood and from the various organs of the body to determine how rapidly the drug is eliminated after it has been given intravenously or orally. It is the purpose of this presentation to give a preliminary report of these findings and to present an eight-year follow-up study of the ambulatory treatment of auricular fibrillation and the method used.

Dogs weighing about twenty kilograms were mainly used in our animal experiments. A few rabbits were also used. Amounts of quinidine up to 600 milligrams were given intravenously to these animals, and samples of the blood were taken at intervals of five minutes or more after the injection (Table I). It was found that the drug was eliminated from the blood stream very rapidly. Less than 6 per cent of the quinidine was found in the blood samples taken seven minutes after the drug was injected intravenously. Repeated samples of the blood taken for several hours after did not reveal any trace of the drug. These findings are in accord with those of Weiss and Hatcher.[2] Working with cats, they showed that 95 per cent of quinidine given intravenously was eliminated from the blood in about five minutes. Hatcher and Gold[1] examined the blood of three patients who were given 650 milligrams of quinin (an isomer of quinidine) intravenously. Samples of blood were taken six to twenty minutes after the injection. They state

that "none of the three contained more than a fraction of a milligram, showing that much of the greater part of the quinin injected had left the circulation."

Since quinidine is usually given orally in the treatment of cardiac disturbances in rhythm, especially in auricular fibrillation, it was believed desirable that a study of the excretion time of quinidine from the blood be made after the drug was given by mouth. This study was carried out mostly on patients. Two groups of patients were used. In the first group, each patient was given a single dose of quinidine. In the second group, each patient was given quinidine in repeated doses one hour apart. It was the purpose of this experiment to see if there was any difference in the excretion time of the drug in the two groups. Were there any accumulative effects when quinidine was given in repeated doses at short intervals?

Eight patients were given single doses of quinidine in amounts up to 10 grains. Examinations of the blood taken thirty minutes after administration of the quinidine showed that less than 10 per cent of the drug was left in the blood. Samples of the blood taken one hour after ingestion of the drug showed no evidence of quinidine. In other words, after giving quinidine by mouth in single doses, over 90 per cent of the drug had left the blood in thirty minutes, and practically all of the quinidine was eliminated from the blood at the end of one hour (Table II).

Six patients were given from 3 to 10 grain doses of quinidine at one-hour intervals, amounting to a total of ten to thirty grains for each patient (Table III). Samples of blood taken one half-hour after the last dose showed that on the average about 20 per cent of the drug was present in the blood. At the end of one hour about twice as much quinidine was present in the blood as there was at the end of the first half-hour. However, ninety minutes later—that is, one and one-half hours after the ingestion of the drug—no quinidine was found in the blood. This shows that (Fig. 1) when the drug is given in repeated doses at short intervals, there appears to be an accumulative effect, or the excretion time of the drug is delayed. The height of concentration of the drug in the blood is reached in thirty minutes or less after a single dose is given, but when the quinidine is given in repeated doses at short intervals of one hour, the point of maximum concentration of the drug in

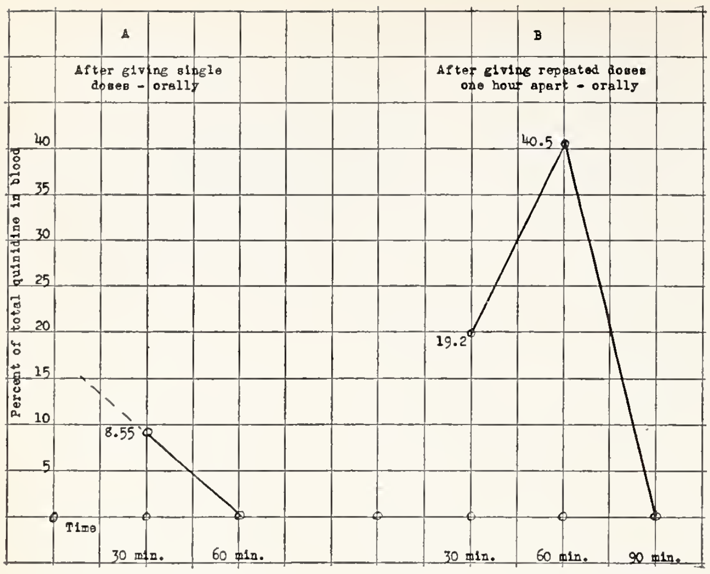

Fig. 1. Concentration of quinidine in blood (human).

the blood stream is reached in sixty minutes or less after the last dose is given.

We believe the error in carrying out this work is not great. We used a burette devised by Dr. A. D. Hirschfelder of the Department of Pharmacology, whereby quantities of quinidine as small as 0.0005 of a milligram can be determined.

This study suggests that it is perhaps better to give frequent small doses for a more favorable result. When this is done, there appears to be a more gradual increase in the concentration of the drug in the blood and also a more gradual elimination of the drug from the blood. It is perhaps for this reason that in our experience very few patients have complained of any toxic effects.

I started out by saying that in 1935 I gave a five-year follow-up study on the ambulatory treatment of auricular fibrillation with quinidine. I shall now give an eight-year follow-up study.

To date Mr. Or, Mrs. M., and Mrs. G., three patients who were in the group of seventeen cases reported in 1932,[4] are still regular. Mr. Or and Mrs. M. have now been regular for seven years, and Mrs. G. has now been regular for eight years (Table IV). Mr. B. died last year following on operation upon an aneurism of the popliteal artery. He had been regular for six years. I have lost track of Mr. P., who in 1937 had been regular for six years. These last two cases were reported as regular in 1936.

The three cases heretofore mentioned are very grateful for their marked improvement since their hearts have been beating regularly. They were more or less invalids for periods of six months to three years before starting treatment. For the past seven years in two cases and eight years in one case, these individuals have been self-supporting and useful citizens. They have reported diligently almost every month for a check-up. They have been taking digitalis and quinidine all this time. As I said before, I believe that if more of the cases originally reported could have been followed up as closely as these three, I have no doubt that I should have had a larger number who would still be regular.

I believe the method that we use in giving quinidine is very important for two reasons: (1) the patient is more apt to establish a tolerance for the drug; and (2) the method tends to eliminate the toxic symptoms we hear so much about that are attributed to quinidine.

Two things should be kept in mind. First, begin with small doses, and, second, repeat doses at short intervals. Our clinical experience with some 200 cases, treated in the cardiac clinic at the University of Minnesota, leads us to believe that quinidine is a very valuable and effective drug in the treatment of this disease. We believe that quinidine should be given in small doses to start with and the dose increased daily and very slowly. In repeating the dose of quinidine, give it at one-hour intervals until the total amount desired is given, then quit for that day. Another very important point is first to digitalize the patient. The heart rate must be slowed down to about 80-70 before starting the use of quinidine. After the heart rate has slowed down, keep the patient on a maintenance dose of digitalis (usually one U.S.P. cat unit) all the time during the treatment with quinidine.

I will again repeat the method we use in giving quinidine in ambulatory cases for the treatment of auricular fibrillation. Give as follows: first day, one dose of 1.5 grains (0.1) at 8 A.M.; second day, 1.5 grains (0.1) at 8 A.M. and at 9 A.M. Then continue as shown in Table V.

If the heart has not returned to regular rhythm after giving thirty grains of quinidine for a few days, I discontinue its use. I have found that, if it takes much more than thirty grains to restore normal rhythm, it is very difficult to maintain a normal rhythm.

After the heart is restored to normal rhythm, gradually cut down the dose of quinidine, say about five grains daily until the patient gets about fifteen grains a day. The maintenance dose can

TABLE IV

Name	Etiology	Age	Duration of Fibrillation	Regular
Mrs. Or.	Coronary	60	6 months	7 years
Mrs. M.	Rheumatic	53	3 years	7 years
Mrs. G.	Hypertension and Coronary	70	2 years	8 years

TABLE V. METHOD OF GIVING QUINIDINE

Day	Time of Dose			
	8 A. M.	9 A. M.	10 A. M.	11 A. M.
1	0.1 (1½ grain)			
2	0.1	0.1		
3	0.1	0.1	0.1	
4	0.1	0.1	0.1	0.1
5	0.2 (3 grains)	0.2	0.2	
6	0.2	0.2	0.2	0.2
7	0.33 (5 grains)	0.33	0.33	
8	0.33	0.33	0.33	0.33
9	0.33	0.67 (10 grains)	0.67	
10	0.67	0.67	0.67	

be ten grains or even five grains in some cases. Usually five grains for two doses one hour apart is the average maintenance dose. This maintenance dose can be kept up indefinitely, together with digitalis.

Conclusions

1. About 95 per cent of the quinidine given intravenously leaves the blood in about seven minutes or less. When quinidine is given intravenously (to dogs), less than 6 per cent of the drug remains in the blood at the end of seven minutes.

2. Quinidine given by mouth in single doses reaches its maximum concentration in the blood in thirty minutes or less and leaves the blood before one hour.

3. When quinidine is given orally in repeated doses, it reaches its maximum concentration in the blood in one hour or less and is all eliminated in one and one-half hours.

4. It appears that quinidine is accumulative in the blood when given in repeated doses one hour apart.

5. An eight-year follow-up study on the ambulatory treatment of auricular fibrillation is presented.

6. Our method of treating auricular fibrillation with quinidine is again presented.

I wish to express my appreciation to Dr. A. D. Hirschfelder of the Department of Pharmacology for his valuable suggestions and aid in carrying out the chemical procedures for the quantitative analysis of quinidine in the blood and tissues. The method used will soon be published elsewhere.

POWERS AND DUTIES OF TOWNSHIP BOARDS OF HEALTH IN MINNESOTA

O. C. PIERSON, Director
Division of Administration, Minnesota State Board of Health
Saint Paul, Minnesota

VARIOUS governmental divisions and forms of local government are provided for by the Minnesota statutes. The governing body of a county is the Board of County Commissioners. The governing bodies of cities and villages are the local councils, and for a town the board of supervisors. The statutes provide for local boards of health under each of these divisions of the local government. County boards of health are appointed by the boards of County Commissioners. City and village boards of health are appointed by city and village councils. The town board of supervisors itself, according to the statutes, must also serve as a board of health for the town, and in effect therefore acts as two separate and distinct boards composed of the same personnel, one board being the general governing body of the town, and the other the town board of health. The powers and duties of the governing bodies and of the boards of health for each of these governmental divisions are prescribed by the statutes.

When a question of public health procedure arises within a town, the town board must determine what the laws and regulations provide for such procedure. If its duty in the matter is found in the laws or regulations pertaining to the duties of local boards of health, then the board acts in that matter as a board of health, just as a city or village board of health would be required to act in a city or village. If its duty lies in the laws pertaining to the powers and duties of town boards of supervisors, then it should act as the board of supervisors and not as the board of health. The State health authorities are not qualified to advise members of boards of supervisors as to their duties as members of such boards. But they are qualified to advise them as to their duties as members of town boards of health.

There is one particular difference between the organization and duties of town boards of health and of city and village boards of health. The statutes say that one member of a city or village board of health must be a physician, who shall be the health officer of the city or village and the executive of the local board of health. Another part of the statutes says that if no member of the town board is a physician, the town board shall appoint a physician as health officer for the town. Another part of the statutes says that all local health officers shall enforce all health laws and regulations and obey the directions of the State Board of Health in the control of communicable diseases. But still another part of the statutes says that for towns the chairman of the town board shall see to it that all necessary things are done to control communicable disease and to enforce the state health laws and regulations. This last provision seems to be contradictory or inconsistent with that other provision which says that it is the duty of all local health officers to enforce all health laws and regulations.

Based on the opinion of the Attorney General's department, the State Board of Health interprets these various parts of the statutes to mean that the medical health officer of the town is to perform those medical functions which the town board or its chairman, not being physicians, are unqualified to perform, and then, upon the findings and advice of the medical health officer, the chairman of the board must see to it that the laws and regulations relating to the matter are carried out. This opinion has been uniformly accepted. It is probable that the establishment or release of quarantine by the medical health officer of a town would be legal, but the actual responsibility for it rests with the chairman, and possibly only the chairman or the town board as a whole could be successfully prosecuted for failure to establish and enforce the quarantine and other control measures which the health regulations require.

While the appointing of such a medical health officer for the town is mandatory, many boards for one reason or another have not done it. No attempt has been made to compel them to do it if in each instance, when such medical services are necessary, the board or chairman employs a physician. That is accepted as complying with the spirit of this law.

The law says that a city *must* and a village *may* provide for a board of health with one member a physician and such physician the health officer, but that if a village has not provided for a legal board of health, then the town board of health of the town in which that village lies must look after the health affairs of that village. Under such conditions the village is responsible to the town for any expense the town incurs in looking after such village's health affairs.

The law says that the compensation of all local health officers shall be prescribed by the body appointing them and, together with their necessary expenses, paid by the municipality or county they serve. This seems to cover compensation for medical health officers of townships as well as villages and cities, but does not seem to definitely provide for compensation to the chairmen of town boards of health. However, town boards may legally pay their chairman for his services as chairman of the Town Board of Health.

The law also provides for a county board of health and a county health officer and says that such health officer must look after the health affairs of all unorganized towns within the county. He has no direct authority in organized towns or villages or cities except to advise with the health officials of those places.

Three matters on which there is much lack of understanding on the part of local and county boards, physicians, attorneys, and sometimes even county attorneys, are:

1. Expenses in the control of communicable diseases;
2. Dealing with dangerous cases of tuberculosis;
3. Abatement of nuisances.

To consider these three in order:

Expenses in Control of Communicable Diseases

The law says that the chairman of a township shall employ at the cost of the town all medical and other help necessary in the control of communicable disease, and, upon receiving a properly itemized statement of such expenses, the county shall reimburse the town by one-half of the amount. If the County Board refuses to so reimburse the town, the town board may appeal to the District Court. If the Court then finds that the expenditure was necessary and as authorized by the law, it will order the county to pay the town one-half of such amount.

It should be noted that this law refers specifically to *"expense necessary to control"* communicable disease. If the town board or its chairman incurs expense which is not "necessary to control," then such expense is not authorized by this particular law and the county is not responsible under this law for the reimbursement of any part of it. Medical treatment, nursing, medicines, food, fuel, etc., are not as a rule necessary for the control of the disease but usually are for the comfort and relief of the patient. If the patient, or his parents or guardians, are not financially able to provide such things, then the providing is a matter of poor relief. The fact that the need for such things arises largely because the patient is afflicted with a communicable disease, and if well he would be able to provide for himself, does not alter the matter. Such things are "poor relief" regardless of the nature of the sickness. It may possibly be the duty of the town board to provide such relief, but, if so, they do it as the board of supervisors and not as the board of health and not under any authority conveyed in these sections of the law relating to expenses in the control of communicable diseases.

But considerable latitude should be given when determining the purpose of such relief and what expenditure is necessary and legal for the control of communicable disease. That such expenditure may help cure or relieve the patient may be immaterial if it also tends to protect the public from infection. And so expenditures for vaccination against smallpox, immunization against diphtheria, curative doses of antitoxin, surgical removal of tonsils from persons in whom virulent diphtheria bacilli persist for a long time, and surgical removal of certain internal organs from permanent typhoid fever carriers, may be legitimate because they result in preventing sickness and making those treated no longer a menace to the public. Likewise expenditures for hospitalization in some diseases and under certain conditions may for the same reason be legitimate. This last is true for tuberculosis where home and living conditions are such as to make hospitalization (preferably in a tuberculosis sanatorium) quite necessary to remove that source of danger to the public.

Examination of suspected cases of the communicable diseases, taking of cultures and other specimens for laboratory examination, and examination to determine if quarantine may be discontinued, are obviously necessary and proper steps for the control of the disease.

But the town board cannot be compelled to pay for any services or expenses, however necessary they may have been to control communicable disease, unless they were ordered by the board or chairman. Frequently a physician is called by the family and treats members sick with communicable disease. Some of his service is necessary in control, and if he had not done it, it would have been necessary for the town's medical health officer, or some other physician employed by the town board of health, to do it. The family being poor, the physician sends his bill to the town board. If the town board has not provided a regular medical health officer to give such service, it would seem that it should authorize such service of that attending physician as by its authority, and pay that part which was necessary to control the disease, instead of escaping a necessary expense on the technicality that the service was not ordered by the board. Had such service been delayed until the chairman had employed a physician to visit the case, the danger of spread of the infection to other residents of the town would very likely have been increased. But physicians should always make it a point to first secure the chairman's order if they expect the town to pay for any of their services.

Dealing with Dangerous Cases of Tuberculosis

It should be borne in mind that tuberculosis is a communicable disease, and that the law which says the chairman shall employ all help necessary to control communicable diseases applies to tuberculosis. Other laws which relate especially to tuberculosis say that if a health officer finds a case of tuberculosis which is endangering the public he may report the facts to the Board of County Commissioners, and that board may then commit the case to a tuberculosis sanatorium. If that county has its own county sanatorium, the County Board naturally will send the case there; otherwise it may send it to a sanatorium maintained by some other county. If the County Board so commits the case, the county will pay the necessary maintenance costs. But this law does not say the County Board "must," it says, "may," and for some such cases County Boards have refused to so commit and pay maintenance costs. If the County Board refuses to so commit, the local health officials must proceed under those laws which relate to expenses in control of communicable disease, and usually the most effective and cheapest way of doing it is to send the case to a sanatorium and pay the necessary cost of maintenance. This cost is a necessary expense in the control of communicable disease, and the town has a just claim against the county for one-half of the amount. So if the County Board commits the case the county pays all the costs. If the County Board fails to commit, it must nevertheless reimburse the town for one-half of the costs if the town health officials do their duty in controlling the spread of the disease through isolation or quarantine of an infectious person in a sanatorium or other proper place.

The Abatement of Nuisances

The law says that when any nuisance, source of filth, or cause of sickness is found on any property, the health officer of the city, village *or township* in which it is, shall serve an order on the owner or occupant of that property, to remove the nuisance. If such order is not obeyed, then the health official shall have the nuisance removed or abated and report the cost of doing it, which must not exceed $25.00, to the town, village or city clerk, who shall certify the amount to the County Auditor. The County Auditor shall assess the cost on the tax roll against that property, and, on receipt of the tax money, reimburse the town. It seems clear from the language in this law and the cost limitation, that local boards of health, health officers, or chairmen are not empowered to condemn buildings or businesses or say where this or that may be located or carried on, but only are empowered to compel cleaning up, removal of offensive matter, the cleaning out, repairing and fly-proofing of privies, cesspools, etc., which, if their order on the owner or occupant of the premises is not obeyed, they can carry out at a cost not to exceed $25.00. The only penalty in this law for failure to obey such order is the taxing of the property in an amount necessary to carry out such order, but not in excess of $25.00. It would be unfortunate if there were no other provisions in the laws for the abatement of nuisances, but other sections of the laws authorize city and village councils to adopt and enforce nuisance ordinances. By such ordinances they may prohibit the location of, or doing, certain things in the municipality or in certain parts of the municipality, and may regulate their construction and maintenance. An ordinance may make it the duty of the health officer or of the village marshal (preferably the latter) to enforce the ordinance. Under such ordinances the citizens will know what they may and may not do, violations will be misdemeanors and arrests may be made and fines imposed. The adoption of such ordinances is the most effective way of dealing with the nuisance problem, and if their enforcement is made the duty of the local police officials it will largely relieve the health officer of duties which are often onerous and do not require medical qualifications. The duty of the local health officer to act under the state law will still remain if the ordinance provisions are not enforced and nuisances exist.

Unfortunately, this power to adopt ordinances does not extend to *towns* since town boards do not have power to adopt ordinances. Very frequently there are nuisances in towns which cannot be effectively abated by serving and enforcing orders to clean up as provided for in the state law. In such cases the final remedy seems to lie in an appeal in the courts by those affected by such nuisances. Such appeal is provided for under another section of the statutes which says that any one affected by a nuisance may bring an action in the courts and the courts may issue injunctions and award damages.

For the purpose of this discussion we may divide nuisances into two classes:

1. Private nuisances
2. Public nuisances

In considering the first of these, *private nuisances,* health officials should understand that it is not their duty to deal with nuisances that may properly be construed as strictly "private nuisances." Private nuisances are such as affect only one individual or family, and in no way involve the health, comfort or general welfare of the rest of the town or that section of the town. But the distinction between a "private" and a "public" nuisance may not always be easy to draw. An insanitary privy, cesspool, manure pile, garbage accumulation, or other similar small nuisance condition, may primarily and particularly affect only one or two individuals or families, but also may affect the general decency, welfare or health of the whole town, or a considerable section of the town. It then should properly be considered a public health nuisance and be dealt with under the provisions of the public health nuisance laws and ordinances. Strictly private nuisances, such as spite fences, etc., which have no general public health significance, may only be dealt with by the courts through private action in the courts.

Public nuisances, for the purpose of this discussion may be subdivided into three classes:

1. The ordinary nuisance of the public health type;
2. The offensive trade nuisance;
3. The state-wide or sectional nuisance.

The ordinary public health nuisance includes such things as privies, cesspools, dumps, garbage, pigpens, dead animals, etc. Although these may primarily only affect one or a few people, they also affect the community as a whole. Insofar as the laws give authority for it, health officials should deal with them, and village and city councils should adopt ordinances to control them.

The offensive trade nuisance is also subject to control by the health officials under the general nuisance laws and regulations, but in addition there are special laws relating to offensive trades. These special laws say that no one may operate an offensive trade except under written permission by the board of health of the town, village or city in which located. A severe penalty is provided for operating without such permit. Whether a business or occupation is or is not an "offensive trade" is not always easy to say. The laws relating to them do not definitely define what an offensive trade is, nor have the courts done so. Each case must be determined on its own individual merits, and this may be a matter which requires legal advice or possibly decision of the courts. It is generally accepted that just because in certain occupations there are odors which are more or less disagreeable to some persons living or working in the vicinity, such occupations are not necessarily to be classed as "offensive trades." Otherwise it might be necessary to require offensive trades permits for such things as tire repair shops, bakeries, meat markets, groceries, canneries, and many other things. The State Board interprets the intent of this law to be, that an "offensive trade" is an occupation in which very offensive and widespread odors are impossible or exceedingly difficult to prevent. In this class may very properly be included such things as rendering establishments, hog feeding and fattening ranches, and, in many cases, slaughter houses.

Statewide or sectional nuisances include nuisance conditions which affect or cover a considerable area of the state and a considerable part of the population. Those who suffer special injury from a statewide nuisance may seek relief in the courts. If a county is particularly affected, through its county attorney it may bring the matter into the courts, and on behalf of the State, the State's Attorney General may do so.

ULTRAVIOLET THERAPY*

MILAND E. KNAPP, M.D.
Minneapolis, Minnesota

Physics and Physiology

THE wave-length of visible light ranges from approximately 770 millimicrons at the red edge of the spectrum to 390 millimicrons at the violet. One millimicron or μ is one-millionth of a millimeter or one twenty-fifth millionth of an inch. The ultraviolet or invisible radiations of shorter wave-length than the violet then continue to about 10 μ where it overlaps the roentgen radiations. They are usually divided into three groups, the near ultraviolet from 365 to 290 μ, the far ultraviolet from 290 to 180 μ, and the extreme ultraviolet from 180 μ to the range of the x-ray group.

It is important that we understand the variations in wave-length because much of the confusion in the literature concerning ultraviolet radiation has been a direct result of lack of definite information about the exact type of radiation used.

The penetration of ultraviolet rays through the tissues varies with the wave-length although they all are absorbed in the superficial layers. The far ultraviolet (180 to 290 μ) penetrate the dermis only 0.1 to 0.5 mm. This is really only through the stratum corneum of the skin while the near ultraviolet (290 to 365 μ) penetrate 0.5 to 1 mm. according to Coblentz.[2] This is into the stratum mucosum or basal cell layer of the epidermis.

The penetration of ultraviolet radiations through inorganic substances also varies with the wave-length. The short wave limits of transparency of various substances is shown in the following table (after Luckiesh).[6]

	millimicrons
Fluorite	125
Quartz (crystalline)	145
Quartz (fused)	185
Blue rock salt Beyond	225
Light crown glass	295
Blue Topaz	296
Ruby	300
Medium crown glass	300
Light flint glass	305
Blue diamond	315
Emerald	320
Heavy flint glass	340

Thus window glass and especially heavy glass is opaque to most of the active radiations. Quartz is the most practical medium of those transparent to most of the ultraviolet radiations. There are some special types of glass which are transparent to the wave-length of ultraviolet in the region of 320 to 290 mu.

Physiology

The action of ultraviolet radiation is photochemical in nature. There is a definite latent period of several hours before the maximum effect is reached. This is followed by a gradual return to normal. The exact nature of the underlying physiological process is not known but the physiological effects may be listed as follows according to Bachem:[1]

---

*Condensed from a lecture given at the Seminar of the American Congress of Physical Therapy at Chicago, Illinois, September 7-10, 1938.

PHYSIOLOGICAL EFFECTS OF ULTRAVIOLET LIGHT

Local

1. Erythema (with short latency)
2. Ultraviolet conjunctivitis (snow blindness)
3. Vasodilation
4. Pigmentation
5. Blistering (sunburn)
6. Tissue stimulation
7. Germicidal and cytocidal effects
8. Sterol activation

Systemic

1. Sympathetic nervous system stimulated (or depressed)
2. Assimilation and elimination increased
3. Internal secretion increased
4. Calcium and inorganic phosphorus fixed
5. Gastric secretion increased
6. Hemoglobin, erythrocytes and platelets increased
7. Clotting time shortened
8. Blood pressure lowered
9. Resistance toward infection mobilized
10. Toxic effects.

Many and perhaps all of these effects vary according to the wave-length. For example, in general the shorter wave-lengths are more bactericidal. Indeed there seems often to be optimum wave-lengths for the destruction of individual types of organisms. The longer wave-lengths are more pigment forming and those near to visible light produce the best tan. The erythemogenic effect has one peak at about 250 μ and another at about 300 μ. The antirachitic effect also follows a definite wave-length distribution as shown by Coblentz.[3]

It is probable that many of the other effects will follow definite wave-length curves also. These may be determined in the future by spectrographic methods with suitable filters.

Technic

Exact technic is essential to progress in any field and the field of ultraviolet irradiation is no exception to this rule. One of the most powerful impediments to progress in this field has been the lack of specific technical details when results have been reported.

In specifying a technic we must first know the spectral composition of the source of radiation used. This varies, of course, with the type of lamp and the filters used. This information can be secured from the Council on Physical Therapy of the American Medical Association if desired. Secondly, we must give an accurate dosage of radiation. And, third, we must consider the skin susceptibility of the individual patient. In general brunettes are more resistant to ultraviolet, blonds are more sensitive and red heads are the most sensitive.

The dosage is determined by the spectral distribution and intensity of the source, the distance of the source from the part to be treated, and the angle at which the rays strike the part.

Coblentz[4] has suggested that the dosage should be measured in Finsen units. He defines this unit as a "radiant flux of 10 microwatts (100 ergs) per square centimeter per second of homogeneous radiation of the wave-length 2,967A°."

Other units of erythemogenic action have been suggested by other authors.

The most practical unit for the ordinary clinician is the minimal erythema dose. This may be defined as the shortest exposure at a certain distance that will produce a perceptible reddening of the skin which disappears within twenty-four hours. This will vary, of course, with different skin types. However, it is easily determined for any given lamp by exposing small areas on the anterior surface of the forearm to a series of regularly increased quantities of radiation and thus determining the one which causes a minimum perceptible erythema. The dosage varies according to the duration of exposure, the distance from the patient, and the angle at which the rays strike the part to be treated.

The dosage varies directly with the duration of exposure.

The inverse square law states that the intensity of radiation from any point source varies inversely as the square of the distance from the source when the absorption by air is negligible. This means that reducing the distance by one-half provides not twice but four times the dose. And reducing the distance to one-third does not produce three times the dose but nine times the previous dose.

The "cosine law" states that the energy per square centimeter is proportional to a constant times the cosine of the angle made by a line connecting the source and the patient, and the line perpendicular to the patient's body. That constant is the light per square centimeter when the patient is perpendicular to the line joining the light and the patient. This means that the lamp should be as nearly at right angles to the part to be treated as possible.

One must be sure that the rays are not absorbed by ointments, crusts, dressings etc., that cover the part to be treated. The part should be thoroughly cleansed with soap and water if ointments have previously been used. The lamp should be kept clean and checked frequently for efficiency.

Indications

Ultraviolet irradiation has been recommended for such a ridiculously large variety of diseases that it is absurd to name them all or even to imagine that this agent is really of value in them all. However, there are a few diseases where the use of ultraviolet radiation is scientifically correct and a number more where its use is supported by enough clinical evidence to be impressive.

1. *Rickets, Infantile Tetany or Spasmophilia, and Osteomalacia.*—The well-proved ultraviolet effect upon calcium metabolism by the formation of Vitamin D makes its use rational in these conditions.

2. *Tuberculosis.*—Most authorities agree that ultraviolet radiation is useful as an adjunct to the usual treatment (bed rest, food, et cetera in extrapulmonary tuberculosis. This includes tuberculosis of the bones or joints, of lymph glands, of the peritoneum and intestines, and of the genito-urinary system.

In some selected forms of chronic pulmonary tuberculosis many workers think that ultraviolet therapy is indicated while others believe that it is contra-indicated in all forms of pulmonary tuberculosis.

3. *Erysipelas.*—In my opinion ultraviolet irradiation is the method of choice in the treatment of erysipelas. The mode of action is not yet understood but the clinical results can no longer be doubted. We have treated more than 500 cases by this method with very satisfactory results.

However, it is extremely important that heavy doses of ultraviolet be given in the treatment of erysipelas—six to twenty erythema doses being used according to the type and efficiency of the lamp employed.

4. *Certain Skin Diseases.*—Many dermatologists employ ultraviolet as an aid in the treatment of certain skin affections. Among these may be listed lupus vulgaris, scrofuloderma, pityriasis rosea, psoriasis, acne vulgaris, adenoma sebaceum, erythema induratum, and alopecia areata.

5. *Indolent Ulcers.*—Some well-controlled work has indicated that ultraviolet is of value in the treatment of indolent ulcers and to promote the healing of wounds in general. This includes the use of ultraviolet in the treatment of chronic draining sinuses, decubitus ulcers and such conditions when it is possible to reach the affected areas with ultraviolet radiation. It is important to use small doses.

6. *Burns.*—Following extensive burns the healing period may be greatly shortened by the use of ultraviolet radiation according to Peck.[7]

7. *Tonic Ultraviolet.*—In many chronic diseases where malnutrition or deprivation of sunlight due to hospitalization is a factor, the use of ultraviolet radiation is indicated for its tonic and psychological effects, as well as its antianemic effects. It may also aid in the prevention of bed-sores. In this group may be included sufferers from arthritis of any type, paralysis, multiple sclerosis, neurasthenia, hemiplegia, and many other chronic conditions. However, "as far as normal persons are concerned, the claim that exposure to ultraviolet rays increases or improves the tone of the tissues or of the body as a whole, stimulates metabolism or tends to prevent colds has not been conclusively substantiated" according to the Council on Physical Therapy of the American Medical Association.[5]

Contraindications

The use of ultraviolet radiation is generally agreed to be contraindicated in active and progressive forms of pulmonary tuberculosis, hyperthyroidism, diabetes, highly nervous people, patients with advanced cachexia or inanition and aged people with acute or chronic nephritis or myocarditis.

It is also contraindicated in certain skin diseases. These include: all forms of generalized dermatitis, lupus erythematosus, herpes simplex, erythema solare perstans, xeroderma pigmentosum, hydroa estivale, freckles, atrophy, keratoses, and prematurely senile skin.

PERFORATING WOUNDS

JOHN M. CULLIGAN, M.D.
Saint Paul, Minnesota

ACCIDENTS which produce perforation of the large cavities of the body are serious and tax to the utmost the judgment and technical ingenuity of the surgeon. The mortality is necessarily high due to the fact that vital organs are frequently involved in the perforation and there is always the danger of infection.

"When in doubt, do not operate immediately" is a fairly good maxim to follow when dealing with obscure diseases. However, the converse is very definitely true when dealing with any perforating wound. The dictum "When in doubt, operate" is the much safer procedure. If the perforation has only resulted in a wound of the abdominal or chest wall and if no vital structures are injured, no harm is done by a simple incision to ascertain the extent of injury (Cases 1, 2 and 3). On the other hand many patients who have perforating wounds of vital organs may not appear ill when first seen. Delay until the patient appears ill results in a great increase in both mortality and morbidity. The dangers of increasing shock, hemorrhage and infection are multiplied with every hour of delay. Therefore, immediate exploration should be the rule in dealing with wounds of this nature.

Food Ingestion

Injury sustained to the gastro-intestinal tract shortly after a large meal carries more risk from perforation and spread of infection than when the stomach and small bowel are relatively empty. Soiling and infection of the peritoneum combined with the peristalsis attendant upon digestion all play a part in making the prognosis more grave.

Anesthesia

For first-aid treatment it may be well to employ no anesthesia at all. In cases of hemorrhage, a spurting artery should be clamped. A gaping wound with oozing may be packed. A chest wound may be closed hurriedly to relieve asphyxia and the attendant suffocation. Measures of this nature may be undertaken with no anesthetic or a little novocaine while waiting for the operating room to be prepared. The choice of the anesthetic to be employed for the major exploration is ether, or nitrous oxide and ether. Ethylene has a slight tendency to increase hemorrhage and is, therefore, an anesthetic of second choice in any case where bleeding may be a factor. The attendant shock with its great fall in blood pressure makes spinal anesthesia a poor selection though this may be more theoretical than actual. Spinal anesthesia may only cause a farther drop in blood pressure and increase the manifestations of shock. For this reason I think it should be avoided though at times it may be indicated. I have had no personal experience with intravenous anesthetics in cases of this kind. Local infiltration may be employed if desired but it has the disadvantage of making a thorough exploration difficult or impossible and thorough exploration is always essential so that no perforation or injury to internal organs will be overlooked.

Hemorrhage

It is surprising how often a penetrating wound of the abdomen is accompanied by little or no hemorrhage (Cases 10 and 11) when one considers the number of large vessels which might be encountered. On the other hand perforation of any of the great abdominal vessels usually results in death before any surgical intervention can be employed. Hemorrhage in the mesenteric vessels is usually self-limited because a hematoma forms which of itself favors clotting and cessation. However, any actively bleeding vessel should be litigated and the bowel supplied should be watched for ten or fifteen minutes for viability. If it becomes apparent that the blood supply is impaired, resection must be performed. Hemorrhage from perforation of the spleen (Cases 9 and 13) or kidney (Cases 13 and 14) require splenectomy or nephrectomy. Perforations of the liver are practically impossible to suture and, as the organ cannot be removed, packing tightly with gauze is the procedure of choice.

Location of Wounds and Organs Involved

Chest.—A clear understanding of the physiology of respiration must be in mind in cases involving puncture wounds of the chest wall. Any wound of this character immediately destroys the negative pressure of the pleural cavity and causes a collapse of the lung. In cases of bilateral puncture the resulting pneumothoraces are dangerous in the extreme. Asphyxia and suffocation result from inability of the lung or lungs to expand and aerate the pulmonary circulation. In order to obviate this the chest cavity should be closed immediately by through-and-through sutures so that the pleural cavity is made air-tight. If there are still signs of asphyxia and suffocation, a needle should be inserted between the ribs (Case 5) and air aspirated in order to restore negative pressure and aid the lung in expanding. When, in a perforation of the chest wall, a pneumothorax is complicated by hematothorax (Cases 4 and 7), closure of the chest cavity is equally important in that the pressure of the blood in the closed cavity acts as a hemostatic and stops the bleeding. No attempt should be made to aspirate any fluid until convalescence is well under way (Cases 4 and 7). When the lung itself is lacerated, the case of course assumes much more serious proportions. This is usually evidenced by the appearance of pink frothy blood coming from the mouth. Tight closure of the chest wound and supportive measures in the form of intravenous medication and transfusions are in order. In cases involving the chest wall and diaphragm, the opening in the diaphragm must be closed (Case 9) and if it is detached from the chest wall it must be replaced if possible. I have had no personal experience with injuries to the heart and pericardium. However, cases are reported in the literature where suture of the cardiac musculature and pericardium have been successfully carried out.

The Gastro-Intestinal Tract. — Perforating wounds of the abdomen puncture the gastro-intestinal tract more frequently than any other one organ (Cases 9, 10, 13, 14, 15, 16, 17, 18 and 19). The number of perforations may vary from one or two to twenty or forty or more. A single bullet may cause a dozen or more while a shotgun charge may cause a very large number (Case 9). Immediate exploration is indicated through an incision fairly close to the midline. This is necessary because the perforations in the bowel may lie at a considerable distance from the site of entrance or exit of the bullet and it is advisable to make an incision through which the entire bowel may be examined. Usually the number of openings in the bowel are even in number (Cases 10, 16, 17 and 19), there being usually one exit wound for each entrance wound. If the number of perforations is uneven, careful search should be made for another (Case 16). Perforation may at times be hidden at the margin of the mesenteric attachment and only careful search will reveal it. If the number is still uneven, one should satisfy himself that one of the perforations is tangential (Case 15). If a single perforation is found in the ascending or descending colon, the parietal peritoneum should be incised and the posterior extra-peritoneal portion of the bowel should be examined. The openings should be closed with two layers of Dulox catgut, suturing transversely. The first layer through the mucosa should be an over-and-over running stitch which everts the mucosa. The second layer should be through the muscularis and serosa, using a Lembert suture. The higher in the tract that the perforations occur, the better the prognosis, as the danger of infection increases the farther the wound is from the stomach. Nasal suction should be employed routinely in all cases of perforation of the bowel or where infection is anticipated.

The Spleen.—When the spleen is perforated, splenectomy must be performed along with whatever other surgery is necessary (Cases 9 and 13). Due to the great vascularity of the spleen, much loss of blood and shock usually accompany the wound. Splenectomy usually is not very difficult. When unassociated with perforations of other organs, the prognosis is usually good, provided the patient is explored early.

The Kidneys.—Puncture wounds of one kidney are in about the same category as the spleen as far as procedure is concerned: That is, nephrectomy is indicated (Cases 13 and 14). This, however, requires that the nephrectomy be performed through an abdominal incision inasmuch as the abdominal cavity must be explored at the same time. However, after incision of the parietal peritoneum of the ascending or descending colon and displacing the large bowel medially, nephrectomy can usually be performed without a great deal of difficulty. Prognosis again depends on the amount of damage to other organs and the amount of blood lost.

The Liver.—Perforating wounds of the liver are always serious and the prognosis is always grave (Cases 4, 12, 17 and 19). In my series very few patients who have sustained this type of injury survived. The hemorrhage is usually great and the attendant technical difficulty of controlling it adds to the seriousness of the problem. Suturing is usually impossible and packing is the method of choice and this is usually inadequate. No doubt the factor of "liver shock" also plays a part in increasing the seriousness of the prognosis. Just what "liver shock" is, is not definitely understood, but it must be recognized as a clinical entity.

The Pancreas.—Injuries to the pancreas are also very dangerous. The inaccessibility of the organ for surgery and the necrosis which follows from the liberated pancreatic juice are the main reasons for mortality and a grave prognosis.

The Bladder.—Perforations of the bladder may at times tax one's surgical judgment. Signs of extravasation are usually present and the lack of return of urine on catheterization should lead one to be prepared. No hard and fast rule can be laid down as to procedure but perhaps the method of choice is tight closure of the bladder and postoperative insertion of an indwelling catheter. The prognosis depends on the amount of soiling, the time element and injuries to other organs.

Shock

The picture presented by these patients is usually one of extreme gravity (Cases 4 to 19). Although an occasional individual even when seriously injured may give the appearance of well-being, this is not the rule. There is usually extreme shock, characterized by pallor, cold perspiration, cyanosis, air hunger, a weak, thready, rapid pulse, and a low blood pressure. Therefore the patient must be treated for shock as well as for his injury. It is well to institute intravenous medication of saline with adrenalin during and even before the operation. Preparations for transfusion should be started immediately for administration during or after the operation. It is usually well to keep the patient in the operating room following the operation until the shock is overcome by supportive measures. Ephedrin and hot water bottles are indicated along with the intravenous treatment.

Infection

If the immediate dangers of shock are surmounted and the perforations repaired satisfactorily, the next concern is that of infection. (Cases 4, 9, 12, 15, 16, 17 and 20). Pneumonia, lung abscess, peritonitis, subdiaphragmatic abscess, and pelvic abscess are the commonest infections which may follow. With the advent of infection these are the locations where one should first look in an attempt to localize and treat the sepsis.

Case Reports

The following series of case reports on twenty-one patient illustrate many of the points made above. The case histories are abstracted very concisely and only the most salient points brought out.

A résumé of the mortality in this group of twenty-one cases reveals there were five deaths or approximately 24 per cent.

In Case 9 death resulted from multiple abscess in both the chest and the abdomen following forty perforations in the bowel due to a shotgun charge.

In Case 12, following a stab wound injury to the liver, subdiaphragmatic abscess, general peritonitis and pleural effusion were the cause of death.

In Case 14 death resulted in less than twenty-four hours probably from the shock from loss of blood as he had both hemoperitoneum and hemothorax.

In Case 17 the patient had a perforation of the liver, small bowel and large bowel. Death resulted from general peritonitis, pneumonia and one opening in the bowel in the retroperitoneal portion of the duodenum.

In Case 18 the patient died from the shock following the passage of an iron bar and clothing through his abdomen. In other words, this patient was killed by the accident rather than by complications.

Sliver of Wood in the Abdominal Wall

Case 1.—An eleven-year-old girl, while running, fell on a sliver of wood. It entered the abdominal wall just to the right of the umbilicus and proceeded in a downward direction. A wooden sliver, six inches long, entering the abdominal wall and extending into the right labia majora was removed. The abdominal cavity was not punctured. Uneventful convalescence.

Perforation in Gluteal Region

Case 2.—A 38-year-old man fell over a box and landed on a sharp branch of a tree. It penetrated the gluteus maximus. The patient's general condition was good and when the branch had been pulled out he was brought to the hospital. It was thought advisable to explore the tract because of the possibility of perforation into the pelvic or abdominal organs. On opening the tract it was found to extend only into the deep gluteal muscles. Uneventful convalescence.

Pitchfork Prong Through Wing of Ilium and Abdominal Wall

Case 3.—This thirty-five-year-old farmer slid from a stack of hay. A pitchfork had been placed prongs upward against the stack, and he was impaled on this. A prong entered the region of the right hip and perforated the wing of the ilium. The patient felt it go through the bone. The fork had been pulled out. Exploration revealed that the prong had perforated the wing of the ilium in an upward direction. It had penetrated the abdominal wall and grazed but did not perforate the cecum. Exploration revealed no puncture wound of any intra-abdominal organ. Uneventful convalescence.

Bullet Wound of Right Chest, Lung and Liver

Case 4.—A twenty-seven-year-old negro was shot by a "friend" through the right chest just below the nipple. The bullet had lodged in the right axillary region below the level of the nipple. There was some question whether the diaphragm and dome of the liver had not been seared by the bullet. The chest wound was closed. Hematothorax developed. The patient made a very slow convalescence, but after four months the chest began to clear. In eight months marked improvement was present and the patient was discharged. Twelve months after the accident the chest was normal on examination.

Eleven Stab Wounds

Case 5.—A thirty-year-old man was attacked while sleeping by an enraged manic-depressive relative. Eleven stab wounds were inflicted: three through the left chest wall, one through the right chest wall, two in the throat, one in the left eyelid, one in the ear, two in the wrist, one in the left lumbar region. The patient, when seen, was in extreme shock, gasping for air because of bilateral pneumothoraces. In the dressing room of the hospital the chest wounds were immediately sutured with through-and-through silkworm sutures. A needle on a large syringe was inserted between the ribs on both sides of the chest and air aspirated. Respirations improved, the gasping ceased and the patient was taken to the operating room where his other lacerations were repaired. Supportive intravenous medication was given. Uneventful convalescence.

Thirteen Stab Wounds

Case 6.—This patient was the wife of the patient in Case 5. When she discovered her husband being attacked by a man with a knife, she went to his aid. The maniac turned on her and inflicted thirteen stab wounds. They were located in the face, neck, nose, left lower leg, right medial thigh and arms. The patient was in extreme shock. Supportive measures were started and the stab wounds repaired. Uneventful convalescence.

Bullet Wound of Chest

Case 7.—A sixteen-year-old boy, suffering from asthma, shot himself with a .22 calibre gun. The bullet entered the left chest above the nipple and came out in the axillary line. He was brought to the hospital and did not look ill. His only complaint was slight pain in the chest. His wounds were merely dressed. The chest filled with fluid but nothing was done about it. In three months, x-rays revealed the complete absorption of the fluid and the chest apparently normal.

Bullet Wound of Chest and Lung

Case 8.—A sixteen-year-old boy was shot by a .38 calibre pistol bullet in the hands of an older brother. The bullet entered the left chest in the third interspace anteriorly and lodged beneath the skin in the sixth interspace posteriorly. He was in extreme shock, unconscious, and his pulse thready and skin cold and moist. There was subcutaneous emphysema of the chest wall. The wound of entrance of the bullet was closed. Supportive measures were instituted. The patient ran a stormy course but was much better in five days. The bullet was removed from the back one week after the accident. The patient was discharged three weeks later in good condition.

Shotgun Wound of Abdomen and Chest

Case 9.—This twenty-two-year-old man, with suicidal intent, placed the butt of a shotgun on the floor, leaned over the muzzle and reached down and pulled the trigger. The shot tore away the left upper quadrant of his abdomen and lower ribs and diaphragm. He was brought to the hospital gasping for breath because of a pneumothorax. The bowel was eviscerated. The patient was in shock. Supportive measures were instituted. Through the gaping wound the diaphragm was sutured to the lateral chest wall in a position higher than its normal attachment with through-and-through catgut sutures. Breathing immediately improved. The shredded ends of the tenth and eleventh ribs were removed. A splenectomy was performed. More than forty perforations of the large and small bowel were closed. The left kidney was not removed though shot could be felt in the capsule. A large retroperitoneal hemorrhage had occurred. The wound was closed as well as possible. For a time it seemed as though the patient might recover, but death occurred on the sixteenth postoperative day. The cause of death as reported at postmortem was: (1) local peritonitis; (2) sub-diaphragmatic abscess; (3) left empyema; (4) abscess of left lung; (5) multiple abscesses of left kidney.

It is interesting to speculate on how the defect in the abdominal wall could have been repaired had the patient recovered.

Bullet Wound Through Abdomen

Case 10.—This seventeen-year-old boy, while hunting, was struck by a .22 calibre bullet from a gun in the hands of a friend. The bullet perforated the sacrum and went through the abdomen, lodging in the skin of the anterior abdomen just lateral to the umbilicus. The patient was in shock. On exploration, ten perforations of the small bowel and four through the mesentery were found. The openings in the bowel were closed transversely with two layers of Dulox catgut. Supportive measures were instituted for shock. Uneventful convalescence.

Lacerations of Throat and Abdomen

Case 11.—A young man of twenty-eight years, grieving over the recent death of his wife, slashed his throat and abdomen six times with a razor. He was in extreme shock from loss of blood. Supportive measures were given. The lacerations in the throat, tongue and pharynx were repaired. Evisceration of the bowel had taken place through the abdominal lacerations, but it was not perforated. The bowel was replaced and the abdomen sutured. Uninterrupted convalescence.

Multiple Stab Wounds of Abdomen, Liver and Diaphragm

Case 12.—A twenty-nine-year-old man, while engaged in a drinking brawl, was stabbed by his brother. Three wounds of the abdomen were found, one each in the upper quadrants and one in the right lower. The one in the right upper quadrant had penetrated the liver and diaphragm and penetrated the chest. The wound in the liver was packed and the eviscerated bowel replaced. The patient died on the twelftfh postoperative day. The postmortem causes of death were: (1) stab wounds of abdomen, liver and diaphragm followed by general peritonitis and sub-diaphragmatic abscess; (2) pleurisy with effusion; (3) cloudy swelling of heart, liver and kidneys.

Bullet Wound of Abdomen Performing Spleen, Mesentery and Kidney

Case 13.—A nineteen-year-old clerk in a drug store was held up and shot in the abdomen by a bandit. The patient was in extreme shock. Supportive measures were instituted. The bullet had entered the abdomen in the left upper quadrant and lodged in the lumbar muscles. On exploration through a left rectus incision, it was found that the bullet had perforated the spleen, left kidney and transverse mesocolon. The spleen and kidney were removed and the rent in the mesocolon repaired. After three weeks the bullet was removed from the lumbar muscles. Uneventful convalescence.

Bullet Wound of Abdomen, Kidney and Diaphragm

Case 14.—This thirty-five-year-old man stated that he was rummaging through a tool chest in which was a loaded pistol. It accidentally discharged, striking him in the abdomen. A bullet wound just lateral to the umbilicus on the left was found. The bullet lodged in the skin in the left lower chest posteriorly. Exploration revealed four perforations of the small bowel, which were repaired, one in the transverse mesocolon and one through the left kidney. The kidney was removed after laying the descending colon medially. The patient's extreme shock was treated by supportive measures but he died within twenty-four hours. The postmortem causes of the death were: (1) gunshot wound of abdomen; (2) lacerations of small intestine and kidney; (3) hemoperitoneum; (4) hemothorax; (5) bilateral congestion and edema of the lung.

Bullet Wound of Abdomen

Case 15.—This eleven-year-old boy was shot through the abdomen by a .22 rifle in the hands of a playmate. The bullet entered the right lower quadrant of the abdomen and lodged in the region of the left acetabulum. On opening the abdomen much free blood was found. There were eleven intestinal perforations in all: three in the cecum, one tangential; six in the ileum; and two in the sigmoid. They were all closed transversely. The patient made a good convalescence in spite of an infected wound and was discharged in six weeks.

Bullet Wound of Abdomen

Case 16.—This twenty-six-year-old patient, while attempting to escape the police, was shot just lateral to the left sacro-iliac synchondrosis. The bullet lodged in the skin just to the left of the umbilicus. Exploration revealed a large retroperitoneal hemorrhage, two perforations of the jejunum at the ligament of Treitz and two of the stomach. These were closed. Retroperitoneal exploration did not reveal the bleeding artery. The kidney was not injured. The patient was transfused but died the next day. Postmortem revealed: (1) general peritonitis; (2) left lobar pneumonia; (3) cloudy swelling of the heart, liver and kidneys; (4) acute splenitis.

In this case only one hole was found at first in the jejunum, but on opening into the lesser peritoneal cavity the second was found, showing the value of looking for two holes.

Bullet Wound of Abdomen

Case 17.—This forty-year-old patient, while standing in a beer tavern, was shot by another man for "no reason at all." The bullet entered the right abdomen just below the ribs and lodged in the left hip. It perforated the liver, the ascending colon in two places, the ileum in six places and the sigmoid in two places. These were all closed by double-layered Dulox catgut. The liver was sutured with mattress sutures. Supportive measures failed and the patient died eight hours later. Postmortem causes of death were: (1) general peritonitis from gunshot wound; (2) bilateral bronchopneumonia; (3) congestion and edema of the lungs. One perforation of the retroperitoneal position of the duodenum just distal to the ampulla of Vater had been overlooked at operation.

Massive Perforation of Abdomen by an Iron Bar

Case 18.—This forty-three-year-old man was sleeping beneath a train. The train started and a broken truss rod, protruding from a box car, impinged upon his abdomen and pole-vaulted the car over his body. This iron bar, measuring 1x6x58 cms., was driven through his body in the left upper quadrant of the abdomen. It carried parts of his coat and shirt through with it. He was brought to the hospital with the bar protruding 8 or 10 cms. in front and back. Through a transverse incision from the midline of the abdomen to almost the spine in the back the bar and clothing were removed. The jejunum was completely severed in two places. These were repaired by end-to-end anastomoses. Several rents in the jejunum were also closed. A large rent in the mesocolon was repaired. The wound was closed and a transfusion was given immediately. He rallied well, but died within twenty-four hours.

The postmortem cause of death was: (1) puncture wound of abdominal wall, with multiple ruptures of the small intestine; (2) shock.

Multiple Bullet Wounds

Case 19.—In a gangland war, a man was shot through the abdomen four times in the right lower quadrant, four times through the right arm and once in the right hip. The patient was in shock. Supportive measures were instituted and the abdomen explored. Four perforations of the transverse colon were closed. The liver was slightly lacerated. This was packed. A retroperitoneal exploration revealed a large hematoma but no injury to the kidney. The patient made a slow but uninterrupted convalescence and fled the hospital on the fifty-eighth day after his injury.

Bullet Wound of Left Groin

Case 20.—This forty-three-year-old male, while attempting to flee after a burglary, was shot by a policeman. One bullet singed his hand and one struck him in the left groin. X-rays revealed the bullet lodged in the region of the left acetabulum. The patient began running a septic course, and eight days later exploration was made for the bullet, going between the sartorius muscle and the rectus femoris. The capsule of the hip joint was incised and about a tablespoonful of pus was evacuated. The bullet was removed from the posterior edge of the acetabulum. Convalescence was uncomplicated from then on.

Perforating Wound of Uterus

Case 21.—This thirty-five-year-old woman, in attempting an abortion upon herself, inserted a Couday catheter into the uterus. She perforated the dome and the catheter slipped away from her. She was brought to the hospital, three days later, with all the clinical signs of peritonitis. Exploration revealed a generalized peritonitis and the catheter was found wrapped in folds of the omentum. This was removed and the abdomen drained. The patient had a stormy convalescence but recovered and was discharged from the hospital on the twenty-third postoperative day.

NONCOMMUNICATING CYST OF THE SEPTUM PELLUCIDUM*

With Recovery Following Ventriculography

NATHANIEL J. BERKWITZ, M.D., Ph.D.
Minneapolis, Minnesota

IN THE seventeenth century Sylvius observed in several brains dilatation of the cavum septum pellucidum (fifth ventricle). Verga,[7] in 1851, discovered a cavity posterior to the cavum septum pellucidum which he suggested naming "the sixth ventricle," now known as the cavum vergæ. At the time no clinical significance was attached to these findings.

These two cavities are not always present. In thirty consecutive brains examined at the University of Rochester, Van Wagenen and Aird[6] report that dilatation of one sort or another of the septum pellucidum was demonstrated in eighteen, or 60 per cent. These writers believe that these two cavities are one embryologically, and only in chance variations are they found to develop separately. The cavities may become so distended by accumulation of fluid as to occlude the interventricular foramina and produce hydrocephalus and other neurological changes.

---

*From the Division of Nervous and Mental Diseases, University of Minnesota. Read before the Central Neuropsychiatric Association meeting, Minneapolis, October 7, 1938.

By means of ventriculography, Dandy,[2] in 1931, was the first to make a clinical diagnosis of abnormal dilatation of the cavum septum pellucidum and cavum vergæ. He reported two cases in which the cavities were dilated to an abnormal degree, sufficiently to produce compression of the pyramidal tracts, and marked mental symptoms. He stated that ventriculograms, in such conditions, appear to be pathognomonic of congenital cysts of the cavum septum pellucidum and cavum vergæ, and that with operative treatment a permanent cure can probably be expected.

Van Wagenen and Aird suggest a practical classification of dilatations of the cavum septum pellucidum and cavum vergæ, namely: "(a) noncommunicating, or those that have not established a fistula into the third, or lateral ventricles; (b) communicating, or those that have a fistulous communication with the ventricular system; (c) secondary or acquired dilatation, communicating in type, where the dilatation is but a part of a superimposed internal hydrocephalus from whatever cause." The noncommunicating dilatations may cause such symptoms as are produced by tumors: mental changes, headaches, vomiting, motor paralysis, etc. Communicating dilatations do not produce clinical symptoms, since there is no pressure to occlude the interventricular foramina. Consequently, the conversion of a noncommunicating to a communicating dilatation by means of a fistulous opening relieves the patient and brings about a clinical recovery.

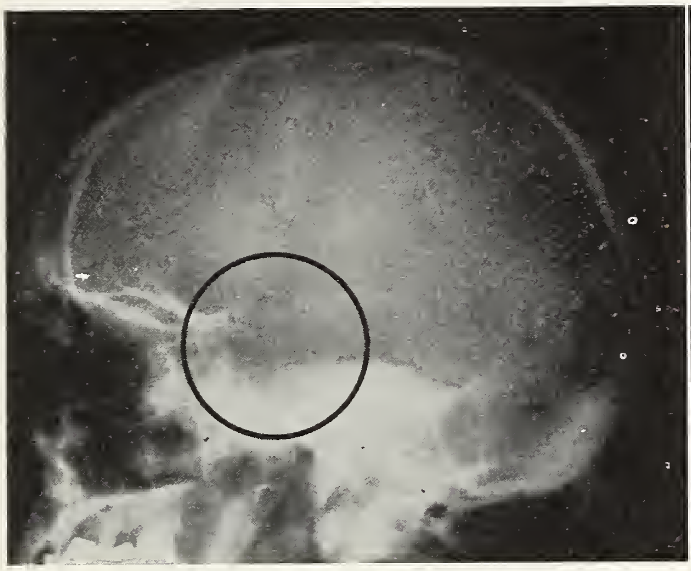

Fig. 1. Skull x-ray, November 14, 1931, showing decalcification of the dorsum sella, erosion of the floor, and enlargement of the fossa.

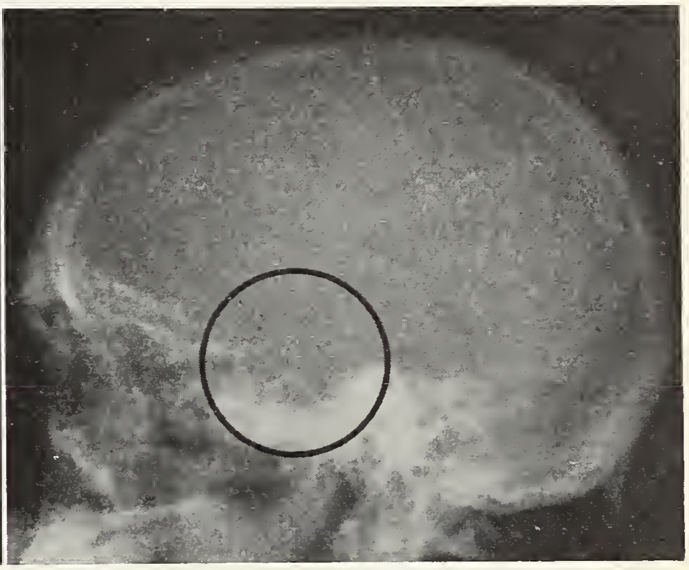

Fig. 2. Skull x-ray, October 31, 1936, showing new bone formation in the posterior clinoids and the clavus, and recalcification of the floor of the sella.

Report of Case

History.—H. K., male, aged thirty-eight, a successful traveling shoe salesman, enjoyed good health up to June, 1931. He first began to have numbness in the right hand, and a few weeks later developed a numbness in the right leg. Early in October a motor weakness appeared in the right extremities. The patient continued to grow worse, became forgetful, irritable, and emotionally unstable, crying and laughing for little or no apparent cause.

On November 1, 1931, the following essential neurological findings were noted: The eyegrounds and cranial nerves were normal, there was incoördination and motor weakness in the right extremities, the deep reflexes were increased, and the abdominal reflexes were decreased on the right. A spinal tap showed the pressure was elevated to 420 millimeters of water pressure. It was decided that he had a left frontal neoplasm and he was taken to a well known clinic for surgical treatment. At the clinic the symptoms continued to increase. He became confused, drowsy, incontinent, and was unable to walk. Skull x-rays showed marked erosion of the sella turcica. A diagnosis of tumor of the anterior corpus callosum was made and, since operative treatment was not recommended, he was discharged.

Examination.—The patient was transferred to the University Hospital, November 13, 1931, in a stuporous condition. He was confused and under the delusion that he had been in an automobile accident one week previous. During the examination he laughed frequently, talked loudly, exhibited Witzelsucht and showed marked paraphasia and motor apraxia. The general physical examination was essentially negative.

The temperature and pulse rate were normal; the blood pressure was 130/80.

Ophthalmoscopic examination revealed mild optic neuritis with engorgement of the retinal veins. Nystagmus was present on looking laterally. All the deep reflexes were increased, but more on the right side. The right abdominal reflexes were decreased, and the Babinski test was present on the right. The patient had coarse tremors of the hands, marked incoördination, and was unable to stand without support.

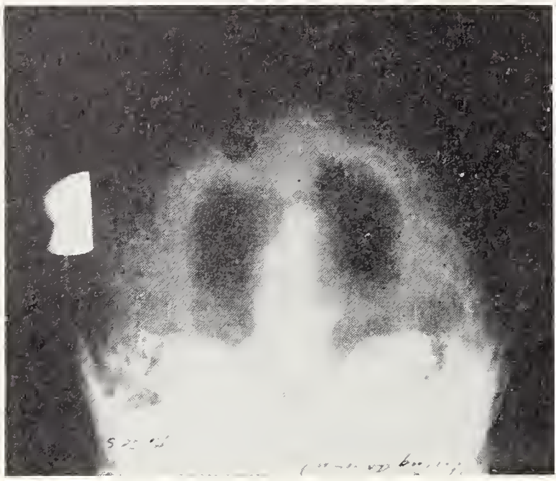

Fig. 3. Ventriculogram, November 17, 1931, anterior-posterior view. Supine roentgenogram showing dilatation of the lateral ventricles with a mass in the midline compressing and separating both ventricles.

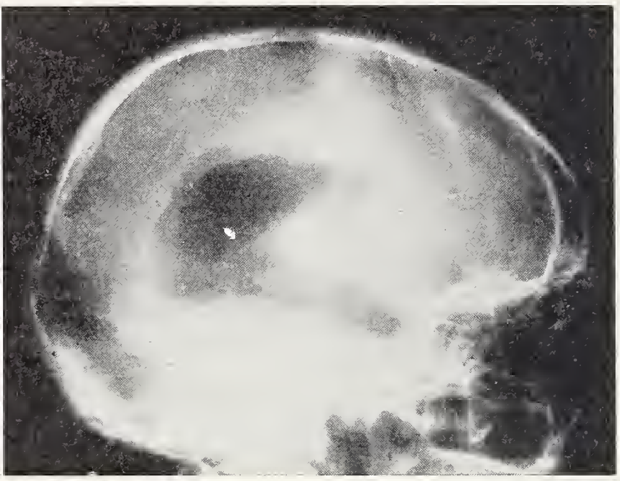

Fig. 4. Ventriculogram, November 17, 1931, right lateral view. Supine roentgenogram showing dilatation of both ventricles with poor filling of the anterior horns.

The blood and spinal fluid Wassermann tests were negative. The spinal fluid was clear, no cells were present and the Nonne test was negative. X-rays of the skull showed a marked thinning out of the posterior clinoid processes, and some irregularity and haziness in the floor of the sella and the neighboring portion of the middle cranial fossa.

Course in Hospital.—As a last resort, a ventriculography was performed by Dr. William Peyton, Head of the Neurosurgery Department, on November 17, 1931. The ventricular pressure was greatly increased; about eighty-five cubic centimeters of clear fluid was replaced by forty-five cubic centimeters of air in the left ventricle, and some methylene blue dye was injected. About thirty-five centimeters of clear fluid was removed from the right ventricle and replaced by twenty-five cubic centimeters of air. No methylene blue dye was recovered in the right ventricle, indicating the presence of a block between the lateral ventricles. The ventriculograms showed both ventricles were markedly enlarged. Instead of a narrow vertical space which normally represents the septum pellucidum, a large filling defect, 5 by 4.5 centimeters, was present.

For two days after the ventriculography the patient's condition remained the same. He tried to get out of bed frequently and to tear the bandage off his head. The third day (November 19) he appeared brighter and less confused. On the sixth day (November 22) he became more rational, cheerful, and coöperative; and on the tenth day (November 27), the day he left the hospital, he was able to walk, feed himself, and talk rationally.

From the ventriculograms, at first a tumor rather than a cyst of the septum pellucidum was considered and two series of eight deep x-ray treatments were given to the head from November 22 to December 7, 1931, and from January 27 to February 15, 1932. Since there was such a definite improvement even before the first x-ray treatment, and since very little, if any, improvement can be expected from deep x-ray treatments for at least two or three weeks, it is beyond all reasonable doubt that the x-ray treatment was not responsible for the rapid recovery.

Since leaving the hospital the patient has enjoyed good health. He returned to his occupation and is working regularly and efficiently. On October 31, 1936 (five years after he left the hospital) x-rays of the skull were retaken. They showed that the floor of the sella remained somewhat deepened and larger than normal, but instead of erosion of the sella turcica there was a considerable filling in of bone, especially in the posterior clinoids and clavus.

Comment

Noncommunicating cysts of the septum pellucidum have been treated successfully by rupturing the cyst wall and producing a fistula into the lateral ventricles. This operation has been performed successfully by Dandy, Van Wagenen and Aird, Tönnis,[5] and Kötter[3] by a transcorpus callosal or a transventricular approach.

Van Wagenen and Aird suggest a less radical procedure be tried first, namely, making a burr hole opening over the right precentral area under a fluoroscope if necessary, tapping the noncommunicating dilatation one or more times with a brain needle, going through an air-filled ventricle.

It is possible for the cyst to rupture spontaneously, since the walls are very thin. Artificial openings between the cysts of the septum pellucidum and the lateral ventricles have been found in autopsied specimens.[2] Two cases have been reported by Van Wagenen and Aird, and Laubenthal,[4] in which they believe communicating cysts were brought about by spontaneous rupture of the cyst wall. Van Wagenen and Aird's case was that of a man, aged thirty-nine years, who had mental symptoms and attacks of unconsciousness. The only neurological findings were a convergence of the right eye and a questionable positive Romberg. The patient recovered after encephalograms were made. The encephalograms showed air in the cavum septum pellucidum which they believe gained entrance through spontaneous rupture of the cyst wall by sudden changes in the intraventricular pressure at the time of the encephalography. They state that Stookey reports a similar experience which leads him to believe that the walls of a septal dilatation were ruptured at the time of an encephalography.

Laubenthal's case was that of a child who developed many neurological findings, and then improved without treatment. Ventriculograms were not made until after the child's condition improved, and these showed a large communicating cyst of the septum pellucidum. Laubenthal believed that the walls of a communicating cyst ruptured spontaneouly, and recovery took place without medical treatment.

The case reported in this paper apparently is also that of the transformation of a noncommunicating into a communicating cyst. The clinical symptoms appeared approximately six months before ventriculography was performed. The clinical picture, consisting of mental disturbances, motor paralysis, drowsiness and motor apraxia with increased cerebrospinal fluid pressure, is characteristic of the corpus callosum syndrome described by Alpers and Grant.[1] The cyst apparently did not rupture immediately, since no air entered the septum pellucidum at the time of the ventriculography. Whether sudden changes of the interventricular pressure, or irritation of air injected was responsible for the rupture of the septal wall cannot be determined, but the rapid improvement immediately following the ventriculography with no recurrence of symptoms after seven years leads the writer to believe that a noncommunicating cyst of the septum pellucidum was ruptured. By repeating the pneumography, positive proof of this diagnosis could be established beyond doubt. The patient refused to give permission for this, but the history, the findings, and the remarkable recovery support the writer's conclusion.

Conclusion

1. Noncommunicating dilatations of the cavity septum pellucidum and cavum vergæ may cause clinical symptoms similar to corpus callosum tumors.
2. The diagnosis may be suspected clinically, but must be confirmed by means of pneumography.
3. The treatment is to convert the cyst into a communicating dilatation by opening it into the ventricular system. Three clinical cases have been reported in the literature where rupture of the walls occurred spontaneously. The writer presents a fourth case. In this case complete clinical recovery followed ventriculography.

Self-Protected—Few physicians die of tuberculosis despite the fact that they are constantly exposed to it. Knowledge defends them as it may yet defend other groups in the population when properly educated in self-protection.

◆ CASE REPORTS ◆

TERMINAL ILEITIS WITH EXTENSION INTO THE CECUM FOLLOWING NONPERFORATING ABDOMINAL TRAUMA

J. S. BLUMENTHAL, M.D., and REUBEN BERMAN, M.D.

Minneapolis, Minnesota

INTEREST in localized areas of chronic inflammation of the small bowel was revived in 1932 by Crohn, Ginsburg and Oppenheimer.[2] These writers named the condition "regional ileitis" although most of their cases conformed to the designation "terminal ileitis." Subsequent studies have demonstrated similar lesions elsewhere in the small bowel and in the colon as well.[3, 4] Etiological factors suggested include tuberculosis, peritonitis from various sources, syphilis, low grade bacterial infection. Inflammatory stenosis of the bowel following abdominal trauma is well known.[5,11] We have, however, found no reports in recent medical literature of blunt non-perforating trauma as the cause of the type of intestinal pathology described by Crohn and his associates.

Bowel injuries from non-perforating abdominal trauma are of great surgical and medico-legal interest. Such injuries are not rare. The injury to the bowel wall may be mild, consisting only in a tear through mucosa or serosa, or severe enough to sever completely the bowel, spilling intestinal contents into the peritoneal cavity. Bruising of the bowel wall with hemorrhage but no actual rent of the bowel may occur. The site of injury may be anywhere in the gastrointestinal tract. Ruptures of the stomach,[5] duodenum,[11] small intestine,[10] appendix,[9] and large intestine[1] have been reported. The terminal ileum lying relatively close to the abdominal wall and partially obstructed by the ileocecal valve is peculiarly vulnerable to trauma. A wave motion set up in the liquid contents of the bowel by a violent blow may rebound from the valve and cause a summation of forces in the terminal ileum. The perforation may occur hours or days following the trauma.[6]

This report deals with a patient in whom terminal ileitis with extension of the inflammation into the cecum developed following blunt trauma to the abdominal wall.

The patient is a white man, twenty-four years old, injured July 6, 1937. His past history is distinguished by many years of uninterrupted good health. Throughout grade and high school he did not miss a day because of illness. He took no sick leave in six years of work. As a child he had measles, epidemic parotitis, pertussis. He uses no liquor or tobacco. His parents, four brothers and three sisters, are living and well. One brother died at eighteen years of Hodgkin's disease. He is married and has three sons, all well. The injury occurred while he and an assistant were lifting empty wooden crates weighing 35 pounds onto a warehouse truck. In raising one of the crates they failed to clear the pile of boxes on the truck and the crate dropped, striking the patient in the right lower quadrant of the abdomen. He suffered immediate severe pain in the region and was incapacitated for work the remainder of the day. The pain lasted about ten minutes and he then was able to go to his car unassisted and drive home. At no time was he unconscious. In spite of pain of short duration recurring every few hours he returned to work the following day. These pains continued until his first operation. He consulted one of us (J. S. B.), on July 15, 1937, because of the pain in the right lower quadrant. At the first examination the only positive finding was a partially absorbed hematoma 3 cm. in diameter located at McBurney's point. Stool examination revealed no occult blood, the urine was negative, white blood count 7,500. On July 19 he was awakened early in the morning with severe pain in the right lower quadrant which soon became intolerable. His temperature was 102 F., pulse rapid and thready, WBC 12,500, urine negative. Acute appendicitis appeared to be the most likely condition and the patient was operated upon later that morning at the University of Minnesota Hospital. A normal appearing appendix was removed. The cecum was normal. Further exploration revealed inflammation of the terminal ten centimeters of the ileum. In this region the bowel was thickened, reddened, and indurated. The lesion included the superior surface and extended around half the bowel circumference. No stenosis and no perforation was found. Peritoneal cultures were taken and with no further ado the abdomen was closed. The cultures were negative. After a rather stormy postoperative course of eighteen days he was discharged with a profusely draining purulent wound. Gastro-intestinal x-ray studies were done September 1, 1937, at the University Hospital. These showed narrowing of the terminal seven centimeters of ileum with a sinus tract extending medially and inferiorly 4 cm. from the midportion of the lesion. The patient continued to have recurrent abdominal pain. Another gastrointestinal study on January 18, 1938, showed a classical "string" sign in the terminal nine centimeters of ileum plus a ragged filling defect occupying the medial inferior portion of the cecum (Fig. 1). A two-stage resection of the distal ileum, cecum and ascending colon was undertaken by Dr. A. W. Hoaglund. At the first stage, January 20, 1938, the terminal ten centimeters of ileum was thick, red and firm. The cecum was less mobile than normal and its medial wall was thickened and hard. The entire ascending colon appeared to be redder than normal. The ileum was divided about 40 cm. from the cecum, the cut ends closed, and a side-to-side anastomosis performed from ileum to transverse colon. Following this operation the patient had an uneventful immediate course but after two weeks began again to have abdominal pain, now aggravated by diarrhea. On March 4, 1938, the abdomen was reopened and the short circuited terminal ileum, cecum, and ascending colon were removed. At this time the mass in the cecum was smaller and the colon more normally mobile. The ascending colon had lost its inflammatory appearance. The patient's immediate recovery was without incident but he has continued to have diarrhea with recurrent attacks of fever of 100 to 102 F. He has not recovered to the point where he can return to work. Careful microscopic and bacteriologic examinations of the diarrheic stools failed to reveal amebæ or B. dysenteriæ. Blood Wassermann tests were negative. The Mantoux test was negative. The patient's claim for compensation on the basis of trauma was allowed by the insurance company.

The operative specimen removed March 4, 1938, consisting of terminal ileum, cecum and ascending colon, was examined by Dr. N. H. Lufkin. The ileum measures 33 cm. from ileocecal valve to the point of amputation. There are a number of old adhesions at the site of the removed appendix. The segment of colon measures 20 cm. along the mesenteric border. The serosal surfaces of both colon and ileum are greatly roughened by recent but definitely fibrous adhesions. These are red and injected. No fibrin is found. The walls of the small intestine feel indefinitely thickened, but the colon on palpation seems normal. In the posterior portion of the cecum on the mesenteric border and within the mesentery are a number of moderately enlarged fairly soft lymph nodes. After fixation the bowel is divided along the antimesenteric border. The ileum seems normal except for increased thickness. Two centimeters from the valve the ileum becomes extraordinarily indurated although the lumen of the bowel is not reduced in caliber. The extreme induration extends to include the orifice of the ileocecal valve. The lips of the valve are extremely rigid with the effective orifice consisting of a slit 12 mm. long and 2 to 3 mm. wide. The stenosis is of a high degree and because of the rigidity incapable of distension. The inverted appendiceal stump is found at a point 2 cm. from the ileocecal valve. In this region the mucous membrane is hypertrophic and verrucous. On the side of the cecum opposite to the valve the mucosa is thickened and indurated, with many closely placed verrucous projections. The margins of the indurated cecum blend gradually into normal bowel distally. The bowel beyond 3 cm. from the ileocecal valve appears entirely normal.

Microscopic.—Sections from the ileum at a distance from the cecum show no changes from normal. Sections of ileum near the ileocecal valve show normal mucosa and muscularis mucosæ. The submucous connective tissues are considerably thicker and more fibrous than normal and there are focal infiltrations of lymphocytes in this layer associated with mild definite active proliferation of the connective tissue cells. The muscular coat is not thickened and practically free of inflammation. The serosa is normal. At a point still closer to the valve the mucosal coat of the ileum is definitely atrophic. The muscularis mucosæ is indistinct and there is extreme fibrosis of the submucous layer. There are large foci of lymphocytes which do not appear to be Peyer's patches. There are also scattered polymorphonuclears, plasma cells and eosinophiles. The muscularis here is greatly thickened, apparently by simple hypertrophy. The serosal coat is likewise thickened and contains dense lymphocytic foci. Sections from the more normal portions of the cecum show no particular changes. In a thickened portion there is some muscular hypertrophy with considerable edema between the muscle coats. This is associated with scattered infiltration of lymphocytes and plasma cells with a few polymorphonuclears. There are small areas of active proliferative changes on the part of the connective tissues but these are not especially conspicuous. Sections from the ileocecal valve and surrounding tissues show marked hypertrophy of the mucosa with the formation of small papillary structures. There is marked increase in submucous fibrosis with numerous perivascular foci of lymphocytes. Lymphoid follicles are extraordinarily conspicuous. There are a few fairly well circumscribed foci of proliferative inflammation associated with giant cells. These lesions do not resemble those of tuberculosis. In the serosal coats there is somewhat less fibrosis than in other sections but dense perivascular foci of lymphocytes are frequent. The lymph nodes show conspicuous lymphoid follicles at the periphery and increase of lymphocytes throughout. There is no evidence of immaturity of the lymphocytes. Polymorphonuclears and plasma cells are unusually numerous throughout the lymph nodes.

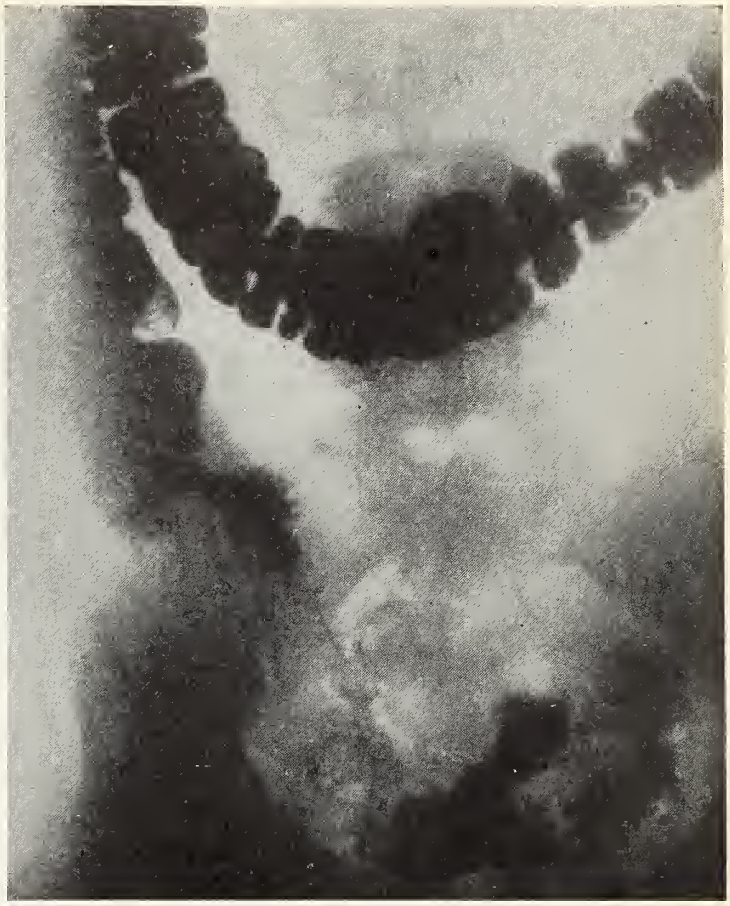

Fig. 1. Gastro-intestinal study of January 18, 1938. Plate taken at five hours showing narrowing of terminal ileum and ragged filling defect of medial inferior margin of the cecum.

Diagnosis.—1. Terminal ileitis with extension into the ileocecal valve and cecum.

2. Chronic stenosis of the ileocecal valve with partial obstruction of the ileum.

3. Hyperplastic mesenteric lymphadenitis.

Discussion.—The pathological appearance of the lesion in the ileum is that of a terminal ileitis. Other etiological factors of stenosis such as tuberculosis, amœbic dysentery, and syphilis, have been ruled out. From the serial roentgen examinations this lesion appears to be primary and the later picture of inflammation in the cecum can best be explained as an extension of the process. It is impossible to prove that the trauma actually caused the lesion. But the evidence in this case favors trauma as the etiological agent. The severity of the injury is attested by the large hematoma in the right lower quadrant over the site of the lesion. There were no symptoms up to the moment of injury, and from that moment on the patient has suffered the symptoms characteristic of this disease.

Summary.—A case of terminal ileitis with extension into the cecum is reported. The distal ileum and proximal colon were excised. The symptoms were initiated by blunt trauma to the abdomen.

DIVERTICULA OF THE STOMACH

WALTER HALLORAN, M.D.

Jackson, Minnesota

DIVERTICULA of the stomach are rare. Among all portions of the digestive tract the stomach is the rarest location of diverticular formations. They are usually found near the cardia, less frequently near the pylorus, while those of the median portion of the stomach along the greater curvature are even less frequently seen.

The following case is reported.

The patient is a woman of fifty-four. Aside from the fact that she had had chronic bronchitis for the past fourteen years and slight attacks of gaseous eructations, there was nothing unusual in her history before May, 1935, when she had an attack of abdominal pain and jaundice which lasted for a few days and subsided. In September of the same year she suffered another attack and was first seen by us. At that time she had been ill for four days with abdominal pain, intermittent in character and very severe, mostly located to the left of the midline. This was associated with vomiting of large amounts which persisted until time of admission. Two months previously she had had right upper abdominal pain, more steady in character and associated with jaundice but no vomiting, which lasted for a few days. She had lost twenty-five pounds during the past two months.

The patient complained of feeling tired and weak, moderate abdominal pain, and said that she had been vomiting all food for the past two days. There were course râles over both lungs. The abdomen showed moderate general tenderness and the liver edge extended about three fingers breadth below the costal margin. There was a smooth rounded mass about the size of a small orange in the right hypochondrium which appeared to be attached to the liver. Otherwise the physical findings were essentially negative. There was no jaundice. The temperature ranged from subnormal in the morning to 99.5 in the afternoon. The pulse was 75, respirations 20, blood pressure 120/70, and the urine showed a faint trace of albumin. The leukocyte count was 10,000. X-rays of the gallbladder showed no filling. A diagnosis of cholecystitis was made. She left the hospital after four days much improved and was to return in ten days for operation. The patient, however, did not return until one year later, when she was brought in acutely ill. About a week before admission she had become acutely ill with a cough, elevation of temperature, and a dull pain in back and abdomen. She noticed that she was jaundiced first the day before admission. She had vomited several times a day for the past two or three days, rather large amounts, and had a chill the day of admission. There was marked icterus, the skin and tongue were dry, temperature 103, pulse 140, respirations 48. She was coughing a great deal and expectorating thick yellow sputum. There were coarse râles over both lungs but no areas of consolidation. The heart was rapid but otherwise normal. A tender, smooth, rounded mass could be felt in the right upper abdomen. Leukocytes numbered 26,000; the urine contained bile and a faint trace of albumin. With forced fluids and ice to the abdomen her condition improved and the jaundice cleared up and the temperature became normal. However, she was still coughing a great deal and the mass in the right upper quadrant persisted. Because of the pulmonary condition it was decided to do a cholecystotomy only.

On opening the abdomen the liver was three fingers breadth below the costal margin with a thickened rounded edge. A smooth mass was attached to the edge and under surface of the liver in the usual location of the gallbladder. It was pink in color and about the size of a hen's egg and covered by omental adhesions. It was densely adherent to the under surface of the liver and gallbladder and was connected to the anterior and upper aspect of the stomach at the pylorus by a pedicle about 2 cm. in length and the size of a lead pencil. The sac was aspirated and contained a thin chylous fluid. It could be compressed slowly. No effort was made to dissect the mass from the liver, but it was resected leaving that portion attached. The wall was about 0.5 cm. in thickness and lined by mucous membrane. There was no connection between the interior of the sac and the gallbladder. The pedicle was ligated at the gastric end and the stump inverted. The gallbladder was contracted and thick walled. There were no stones in the gallbladder or ducts. The gallbladder was drained. She had an uneventful convalescence and left the hospital on the fifteenth day. It was evidently a true diverticulum of the stomach which had become attached to the liver and gave rise to the symptoms simulating cholecystitis.

HISTORY OF MEDICINE IN RAMSEY COUNTY

BY J. M. ARMSTRONG, M.D.

(Continued from May issue)

The Ramsey County Medical Society

Meetings of an informal nature among physicians had been held in Saint Paul since the dissolution of the Saint Paul Academy of Medicine and Surgery in 1866, but no formal organization was attempted. The constitution of the State Society of 1869 demanded the organization of county societies. Those of our local physicians who took the initiative in the formation of the Society were Dr. Charles H. Boardman and Dr. E. Hermann Smith, apparently at the instigation of Dr. Samuel Willey. On February 14, 1870, eleven physicians met in Doctor Smith's office and formed the Ramsey County Medical Society. Doctor Willey acted as temporary chairman, and the following officers were elected:

Daniel W. Hand—President
Alfred Wharton—Vive President
William Banks—Corresponding Secretary
Chas. H. Boardman—Recording Secretary
Samuel D. Flagg—Treasurer

After some discussion, the present name of the Society was adopted, it not being thought advisable to revive the older organization. Drs. Flagg, Banks, and Lawson were appointed a committee to draft a constitution and by-laws, and the Society adjourned to meet one week later. At this second meeting, twelve members signed the constitution, and the secretary was instructed to secure the signatures of other physicians who wished to join. After the following meeting, it was agreed that further additions to membership should be by ballot. The signatures of twenty-two men were obtained before the third meeting. These men are regarded as the founders of the society. The first member admitted by ballot was Dr. Alexander J. Stone, who came to Saint Paul from Stillwater early in the year. The next members were Drs. Charles Hill and William W. Mayo. Both of these men were elected to the State Legislature in 1872, and practiced medicine in Saint Paul as partners during their term of office. In 1873, Doctor Hill returned to Pine Island, and Doctor Mayo to Rochester, where both remained till their deaths. The names of the founders and the order in which they signed the constitution are: William Baldwin, David Day, John Steele, F. R. Smith, Brewer Mattocks, J. H. Stewart, William Banks, E. H. Smith, C. E. Smith, C. H. Boardman, S. D. Flagg, A. G. Brisbine, A. Wharton, J. H. Murphy, Frank Lawson, Adelard Guernon, D. W. Hand, M. Hagan, William Ray, John B. Phillips, T. R. Potts, and Samuel Willey. The Society has portraits of these men, but they were taken at a later date than the year of the founding.

For the first two years of its career the society was in a flourishing condition. Then evidence of decay became apparent, and at the end of its fifth year it practically ceased to exist. After four years of inactivity it was revived in 1879, and

Signatures of members who signed the Constitution.

flourished till 1882 when meetings were fewer and less well attended till 1889. A revival then occurred and the Society had been successful ever since, though there were periods until the year 1900 when attendance at the meetings was smaller than it should have been. Up to the beginning of this century the total number of those admitted was 261, the largest number having been added in 1884 when twenty-three new members were admitted. In 1900, the members numbered 135. At the present time the membership is about three hundred.

The minutes of the Society from the beginning reveal that the meetings were harmonious with but few exceptions. Many interesting papers were presented and intelligent discussion followed the papers and cases presented. At first, the meetings were held in the physicians' offices, and later in the rooms of the Saint Paul Medical School and in various hotels. In 1896, the Society secured rooms on the third floor of the old Lowry Arcade Building which also housed the beginning of the Society library and a laboratory. These rooms were occupied till the present Lowry Building was erected in 1912. Space for the Society's activities was then provided on the thirteenth floor. This was another step in advance and these rooms were occupied till the completion of the new Lowry Medical Arts Building, when the present adequate and attractive quarters were occupied in December, 1930, for which the Society, for the third time, is indebted to the owners of the building.

Among those who have attained prominence in medicine the following* may be mentioned:

1870-1880

Drs. Samuel Willey, Daniel W. Hand, Franklin R. Smith, Chas. E. Smith, Alexander J. Stone, Samuel D. Flagg, John H. Murphy, Alfred Wharton, J. H. Stewart, Francis Atwood.

1880-1890

Drs. Charles A. Wheaton, Edouard Boeckmann, Arthur B. Ancker, Everton J. Abbott, Justus Ohage, Gottried Stamm, Frederick Dedolph, John F. Fulton, Cornelius Williams, James A. Quinn, Jay Owens, Wm. Davis, Anton Shimonek, Perry H. Millard, Talbot Jones, Daniel Leasure, C. Eugene Riggs, Albert E. Senkler, Parks Ritchie, James Davenport, Chas. B. Witherle.

1890-1900

Drs. Arnold Schwyzer, Arthur Sweeney, Henry J. O'Brien, H. L. Nippert, Charles Lyman Greene, H. Longstreet Taylor, Jacob E. Schadle, Archibald MacLaren, Burnside Foster, John L. Rothrock, James S. Gilfillan, Arthur J. Gillette, Warren A. Dennis, E. W. Buckley, A. R. Colvin, Harry P. Ritchie, Gustave A. Renz, Geo. E. Senkler, Haldor Snévé, Thomas McDavitt, John T. Rogers, Walter Ramsey, James T. Christison, John B. Brimhall, Robert O. Earl, Erik M. Lindholm.

The reader will note that the names of none who came later than the year 1900 are included. In addition, may be mentioned Dr. Harry C. Hand who first brought a knowledge of microscopic pathology to Minnesota and who is quoted in Gray's Anatomy (6th edition) for observations on the anomalies of the cardiac valves; Dr. Justus Ohage who performed the first cholecystectomy in this country in 1886; and Dr. Anton Shimonek, who first brought here a knowledge of bacteriologic technic and claimed to have performed the first interval operation for appendicitis in the United States. Of those who had some distinction in other activities may be mentioned Dr. Daniel Leasure, who was a Brigadier General of Volunteers in the Civil War; Dr. Percy Vittum, who wrote a very pleasant little book of poems; Dr. Henry F. Hoyt, the author of an interesting autobiography under the title, "A Frontier Doctor"; Dr. Egil Boeckmann who has served for eight years as Regent of our State University; and Dr. Charles B. Witherle, who after leaving here became professor of nervous and mental diseases in the University of Maine, and Dr. Edouard Boeckmann, who designed the first steam pressure sterilizer.

Laboratory of the Ramsey County Medical Society

With the advent of Dr. H. C. Hand in 1871, the interest in both gross and microscopic pathologic anatomy began to play an important part in the meetings of the Society, and Doctor Flagg in his annual presidential address in 1872 touched on the desirability of establishing a museum for the preservation of interesting pathologic specimens. In 1889, a Pathological Section of the Society was formed and preservation of specimens was begun. In 1896, when the rooms in the Lowry Arcade were obtained, a pathologic laboratory was established for the use of the members. This section of the Society was a very active one for some years, under the supervision of Drs. Hallowell, Renz, Shimonek, and Rothrock. When the laboratory of the Department of Health was established and the various hospitals put in laboratories, the need for the Ramsey County Society laboratory was not so urgent and it fell into more and more disuse. Finally, when the Society rooms were removed in 1913 the laboratory was abandoned as it was then little used and had served its purpose. The remaining specimens of the collection were presented to the laboratory of the Department of Health. While this laboratory section of the Society existed it was of great utility to the members, and an activity which few county medical societies possessed at that time.

---

*The names are arranged in the decade in which they came to Saint Paul.

Laboratory for Making Catgut Ligatures

In speaking above of the pathological laboratory, no mention was made as to how funds were provided to maintain it during its later years. Dr. Edouard Boeckmann had perfected a method of preparing catgut for surgical ligatures for his own use, and as the product soon began to be used by other surgeons, both here and elsewhere, he generously turned over the manufacturing and sale of it to the laboratory committee in order that the laboratory might be financed. All these years, the Society has continued to prepare and sell pyoctanin catgut which has been and is now widely used by surgeons throughout the country. With the abandoning of the pathological laboratory the profits accumulating from this activity now form the principle part of our building fund.

The Saint Paul Medical Journal

The proceedings of our Society may be found in the *Northwestern Medical and Surgical Journal* during the life of that journal, from 1870 to 1874, and from 1881 to 1899 in the *Northwestern Lancet.* At the annual meeting of the Ramsey County Medical Society in January, 1898, it was moved that a committee of five be appointed to consider the advisability of the Ramsey County Medical Society controlling its own medical journal, and to report at a future meeting. In October, 1898, the committee made a lengthy report which ended with the following recommendation: "First, That the committee are of the opinion that the Society should publish a monthly journal, the first number to be issued January, 1899. Second, That the committee recommend that the publication for the first year be delegated to the Committee on Publication with full power to act, with the understanding that the said committee assume all financial liabilities whatsoever."

There was considerable opposition manifested during the discussion following this report, but it was adopted by a small majority. The *Saint Paul Medical Journal* made its appearance in January, 1899, and in November, 1899, was made the official organ of the Society. Although the name of Dr. Edouard Boeckmann does not appear in connection with the starting of the journal, one may state that the idea of starting it originated with him and it was he who agreed to finance it for its initial year.

The *Saint Paul Medical Journal* was a success both financially and scientifically from its beginning till its demise in 1917, when the State Association began the publication of *Minnesota Medicine.* In order to consolidate the medical activities of the state the Saint Paul journal withdrew and offered its resources to the State Association. To those of the Society whose membership began after this journal ceased publication, I suggest that a perusal of it would be profitable and instructive. Dr. Burnside Foster edited the journal and ably conducted it till the time of his death. His editorials may be read with profit today, and no doubt had a great influence in promoting ethical medicine and raising the standard of medical journalism in the United States. Dr. H. Longstreet Taylor was the first business manager, and ably coöperated with Doctor Foster in making the journal a success. Members of the Society received the journal gratis. But few county medical societies then or since have had the temerity to publish a journal of their own.

Library of the Ramsey County Medical Society

For a number of years, the library was supported by voluntary subscriptions. After the *Northwestern Lancet* moved to Minneapolis the exchanges of that journal ceased to come to the library. In 1899, they were replaced by the exchanges of the *Saint Paul Medical Journal.* An annual appropriation for the library was made by the laboratory committee from its profits, and also from the profits of the *Saint Paul Medical Journal.* After the demise of the *Saint Paul Medical Journal,* the burden of supporting the library was born by the laboratory committee with a small appropriation from the Society's funds. The library now receives part of the exchanges from *Minnesota Medicine.*

The library has prospered exceedingly well, but like every similar institution it has always been in need of more funds as its activities expanded. Finally, in 1929, the Society realized that permanent adequate financial provision must be made for its support. In addition to the small annual contribution from the Society an annual appropriation from the income of the building fund of the Society was set aside for this purpose, and at the same time friends of the Society contributed nine memorial funds for deceased members. These latter funds have enabled the library to purchase books and to complete files of periodicals for which the funds of the Society were inadequate. The library keeps on file the important medical journals of the world and many society transactions, and endeavors to purchase any new books of merit which cannot be secured by other means. Many individual members of the Society and others, too numerous to mention here, have contributed books and journals. The library, since the autumn of 1929, has been under the administration of Miss Isabella T. Anderson, a trained librarian, and much progress has been made since then in cataloging and making accessible much material difficult to locate previous to that time. In addition to the library there is also housed in our rooms an extensive collection of antique and obsolete medical and surgical instruments and appliances which make an extremely interesting and instructive display. This collection was initiated during the presidency of Dr. Wallace H. Cole. Practically all this collection has been donated by Society members. The library also is attempting to form an historical collection of important medical books. Since funds are limited for this purpose the committee has largely confined its efforts in this direction to Medical Americana, and up to date has been fairly successful in this effort.

Too much praise for their foresightedness cannot be given to those members who formed the nucleus of the library, especially to Drs. H. Longstreet Taylor, J. L. Rothrock and Edouard Boeckmann, the last mentioned having been very generous in his gifts of books, journals, funds, and counsel. A more extensive account of the origin of the library may be found in Doctor Taylor's article in *Minnesota Medicine* for October, 1931, (Vol. XIV, p. 906). The library now contains over 20,000 volumes.

Building Fund of the Ramsey County Medical Society

The accumulation of a building fund by the Society without outside aid and without expense to any member, is without doubt one of the most remarkable events in the history of this Society and would be of any society. Properly, one should introduce here or at the end of every one of the enterprises of this Society a biography of Dr. Edouard Boeckman, as his biography would include the story of the initiation of all the enterprises of this Society which have been of permanent value. In the year 1901, the American Medical Association met in Saint Paul for the second time, and a considerable sum of money was raised for its entertainment. It so happened that after that convention a sum of money somewhat over $3,000 remained unexpended in the hands of the Entertainment Committee of which Dr. Charles A. Wheaton was chairman. As there was no means of ascertaining the method of disposing of this money, Doctor Wheaton kept it till March, 1904. After legal advice, he then turned it over to a committee of the Ramsey County Medical Society as a nucleus for a building fund. To this nucleus was annually added the small profits of the *Saint Paul Medical Journal,* while it existed, and the profits from the sale of catgut ligatures, except the sums appropriated for the maintenance of the library of the Society.

In 1926, Dr. F. E. Burch acquired in the name of the Society for the building fund the property on Ninth Street belonging to the Saint Paul Free Dispensary, and formerly the property of the Saint Paul Medical College. Aside from this generous acquisition through Doctor Burch the Building fund, one might say, is the result of the enterprise and practically the gift to the Society by Doctor Boeckmann. To show the appreciation of the unselfish devotion of Doctor Boeckmann to our Society, the Fund is now known as the "Boeckmann Library Building Fund." When the fund grows to a sufficient amount to build and maintain a proper home for the Society and care for its library, no doubt the Boeckmann Memorial will be erected.

Seal of the Ramsey County Medical Society

The following quotation from a letter written October 3, 1914, by Dr. Brewer Mattocks narrates the history of the seal of our Society:

> "As to the seal of our Society, we had none until I was elected to an honorary membership on my return to Saint Paul (about 1900), when I was, with the remaining charter members, Drs. Flagg, C. E. Smith and Wharton, appointed to secure the pictures of the charter members. It then occurred to me that we should have a seal and I suggested the legend, "Dissect, observe and write," in the imperative. I wrote Arch-Bishop Ireland to Latinize the motto for me. He was kind enough to send his secretary to me with the suggestion that the imperative be changed to the infinitive, and wrote the legend as it now stands. Drs. Flagg, Smith, and Wharton united with me in presenting the seal to the Society, which was graciously accepted as such, and no questions asked from the surviving charter members."

The seal was designed by R. O. Sweeney. No doubt many of the older members remember Sweeney's Drug Store on what used to be called Bridge Square, at Kellogg Boulevard and Wabasha St.

Doctor Mattocks was mistaken, however, as to the surviving charter members.

He should have included Doctor Boardman who was living in Brooklyn at that time.

Appended will be found a list of presidents of the Ramsey County Medical Society and the names of those who have held the positions of city and county physician, health commissioner, and coroner of Ramsey County.

Presidents of the Ramsey County Medical Society

1870	Daniel W. Hand*
1871	Alfred Wharton*
1872	Samuel D. Flagg*
1873	Charles E. Smith*
1874	John H. Murphy*
1875-79	Charles H. Boardman*
1880	Martin Hagan*
1881	Daniel Leasure*
1882	Daniel W. Hand*
1883	Albert E. Senkler*
1884	Charles A. Wheaton*
1885	James Davenport*
1886	Jay Owens*
1887	Parks Ritchie*
1888	James C. Markoe*
1889-90	Justus Ohage*
1891	Talbot Jones*
1892	William Davis
1893	John F. Fulton*
1894	Arthur B. Ancker*
1895	C. Eugene Riggs*
1896	Arthur J. Gillette*
1897	Jehiel W. Chamberlin*
1898	James A. Quinn*
1899	Edouard Boeckmann*
1900	Gustav A. Renz*
1901	Cornelius Williams*
1902	John L. Rothrock
1903	Angus McDonald*
1904	H. Longstreet Taylor*
1905	Arthur W. Dunning*
1906	Burnside Foster*
1907	Everton J. Abbott*
1908	Arthur Sweeney*
1909	Arnold Schwyzer
1910	Warren A. Dennis*
1911	James S. Gilfillan*
1912	Thomas W. Stumm*
1913	Charles J. Meade*
1914	John M. Armstrong
1915	Harry P. Ritchie
1916	Henry L. Nippert*
1917	James T. Christison
1918	Robert O. Earl
1919	E. W. Buckley*
1920	Charles N. McCloud*
1921	Frank E. Burch
1922	John C. Staley
1923	E. G. Sterner
1924	Carl L. Larsen
1925	E. M. Hammes
1926	C. C. Chatterton
1927	Francis J. Savage
1928	E. M. Jones
1929	Wallace H. Cole
1930	F. C. Schuldt
1931	O. W. Holcomb
1932	E. V. Goltz
1933	Harry Oerting
1934	Frederick J. Plondke
1935	Robert M. Burns
1936	Albert G. Schulze
1937	George K. Hagaman
1938	James N. Dunn

Dr. Alex J. Stone was elected in 1881, but as he was elected at that time president of the State Society he resigned and Dr. Daniel Leasure, vice president, succeeded to the office.

Those members who have served as president of the State Medical Association are:

1869-71	Samuel Willey*
1880-81	Alexander J. Stone*
1882-83	Perry H. Millard*
1888-89	Chas. A. Wheaton*
1891-92	Parks Ritchie*
1894-95	Justus Ohage*
1897-98	John F. Fulton*
1900-01	William Davis
1903-04	Chas. Lyman Greene*
1909-10	Cornelius Williams*
1912-13	Haldor Snévé*
1915-16	John T. Rogers*
1918-19	A. J. Gillette*
1921-22	C. Eugene Riggs*
1924-25	Archibald MacLaren*
1929-30	James T. Christison
1934-35	Francis J. Savage
1938-39	George A. Earl

Saint Paul City Physician and Health Officer

1854 James D. Goodrich
1855-56 Samuel Willey
1857-59 John V. Wren
1859 Jos. A. Vervais
1860-62 Thomas R. Potts†
1862-66 A. G. Brisbine†
June 1866-67 Thomas R. Potts
1867-71 E. Brewer Mattocks
1871 Martin Hagan
1872-74 Thomas R. Potts
1874-80 E. Brewer Mattocks
1880-84 Stewart and Wheaton

---

*Deceased.

1882-84 Stewart and Wheaton

---

*As president of the Saint Paul Academy of Medicine and Surgery.

(To be continued in July issue)

President's Letter

THE State Association meeting will be in progress as this issue goes to press and thanks are due to all who helped in preparations for it, particularly the Committee on Scientific Assembly, the groups from the University, the State Department of Health, the State Board of Control, the Local Minneapolis groups, Minneapolis City Health Department and the Department of Education. Hennepin County will be a fine host as usual and we wish to thank President Reynolds and the other officers, Chairman Cardle, all of his Committee and the Women's Auxiliary for the delightful entertainment they have arranged for this meeting.

The Medical Economics Committee is the largest in personnel of all our committees. It has a definite section in every issue of our State Journal and it deals with the changing social and economic conditions of the last decade coincident to the economic depression of world-wide range. The Committee has had to meet with active propaganda from governmental and liberal groups and it has been the responsibility of the Committee to judge what is and what is not of merit in the proposals set forth.

We have been fortunate in having an experienced and able Chairman, Dr. W. F. Braasch, whose long contact with organization work in the course of which he has served as President of the Association and delegate to the American Medical Association, has enabled him to conduct the work of the Committee with great force. He has had, of course, the help of an able committee composed of several important sub-committees. We have from time to time mentioned the work of these sub-committees and we wish to take occasion in this issue to express the appreciation of the Association to the Medical Advisory sub-committee composed of Dr. B. J. Branton, Dr. W. L. Burnap and Dr. W. H. Hengstler. This Committee has been a direct source of comfort to many of our members. Under Dr. Branton's leadership definite, tangible results have been produced as regards the methods of handling delicate situations and also in promoting a better understanding between the Bar Association and the Medical Association.

Dr. T. H. Sweetser, Chairman of the State Health Relations sub-committee, has worked as hard as anybody in the Association. No one has been more faithful in attending meetings or more conscientious in his handling of difficult situations. His committee has done much toward securing the best possible coöperation between our tax-supported agencies and the private practitioner.

Dr. W. A. Coventry, Chairman of the Committee on Low Income and Indigent Problems, brings to any committee a long experience, great ability and forceful effort. Of all our economic problems, probably this committee on Low Income and Indigent Problems is dealing with the most important. It is upon the groups of low income and on the indigent that recent demands for social change have been directed.

Under the chairmanship of Dr. F. J. Savage, the Committee on Interprofessional Relations have been active, also. It has sought the coöperation, particularly, of the dental and legal professions, and it has worked very closely with Dr. Branton's Committee. The contribution of these committees to our program has been beyond estimation. In other issues we shall have an opportunity to mention others which have also done excellent service.

George Earl, *President,*
Minnesota State Medical Association.

DIGITALIS UNIT CHANGED*

THE fact that the digitalis unit of the last Pharmacopeia of the United States (XI), which became official June 1, 1936, was increased over that of the U. S. P. X has received little attention and is not generally known. The new unit (U. S. P. XI) is the international or Magnus cat unit and is contained in 0.1 gram of the U. S. P. XI digitalis powder or 1 c.c. of the U. S. P. XI tincture of digitalis. This corresponds to 0.17 gram of the U. S. P. X digitalis powder or 1.7 c.c. of the U. S. P. X tincture. In other words, when a physician prescribes 1 c.c. of the new tincture, he is prescribing a dose corresponding to 1.7 c.c. of the older tincture.

The importance of this fact lies not so much in the gradual digitalization of a cardiac patient as in determining the maintenance dose or in determining the amount of the dose required for full digitalization. Whereas 1.5 grains of the U. S. P. X powdered leaf, or 15 minims of the U. S. P. X tincture per ten pounds of body weight, were required for nearly complete digitalization, this would be approximately 70 per cent too strong a dose in the preparations made official by the U. S. P. XI. If a patient eliminated 15 minims of the older tincture daily, he would more likely eliminate nearer 10 minims of the new tincture.

It is said that many pharmaceutical houses are still conforming to the U. S. P. X standard in the manufacture of their digitalis preparations. It becomes important at times to know, therefore, whether a preparation conforms to the tenth or eleventh edition of the pharmacopeia.

GOLDBLATT'S HUMORAL HYPOTHESIS

THE experiments which have been reported in the *Journal of Experimental Medicine* by Goldblatt during the past few years on the production of hypertension in dogs are of interest. By means of an ingenious clamp, he constricts the main artery of one or both kidneys, producing an ischemia of the organ. He has found that so treating one kidney usually results in an elevation of blood pressure which in a few weeks tends to recede and even return to normal. If such a treated kidney is removed while the blood pressure is elevated, the pressure returns promptly to normal. If, however, after the artery to one kidney is clamped, the normal kidney is removed, the elevated blood pressure persists.

If moderate clamping of the arteries to both kidneys is performed, an elevated blood pressure is produced which persists for months and even several years. While the urea clearance of such kidneys is reduced, the function of these kidneys is not otherwise impaired. Extreme clamping of the arteries produces symptoms of uremia. Most interesting is the observation that severing the nerve supply to the kidneys neither prevents nor relieves the hypertension.

---

*For more detailed explanation of the subject, the reader is referred to Correspondence, Journal A.M.A., 112:1180, (March 25) 1939.

Microscopically the kidneys which have had their blood supply moderately reduced show thickening of Bowman's capsule and of the basement membrane of some of the glomeruli. The picture produced resembles that of essential hypertension, although the reduction in the blood supply is produced by narrowing the renal arteries, whereas in essential hypertension the narrowing takes place in the renal arteries.

Applying the clamp to other arteries such as the splenic or femoral, however, does not produce hypertension.

The author concludes from his experiments that ischemia of the kidneys is the common factor in experimental and essential hypertension and, inasmuch as experimental hypertension is independent of nerve supply, offers the hypothesis that ischemia of the kidneys produces some humoral substance in the kidneys which acts in some way, possibly directly on the muscles of the arterioles in general, to produce hypertension.

Goldblatt's idea, as we interpret it, is that generalized arteriolosclerosis causes ischemia of the kidneys which liberates some sort of humoral substance which causes through its action on the arterioles a further narrowing of the peripheral arterial bed, and hypertension follows. The generally accepted conception of a narrowed peripheral arterial bed being the cause of hypertension, is apparently maintained. It does seem as though an arteriolosclerosis sufficient to cause renal ischemia should be sufficient in itself to cause hypertension, without invoking a humoral hypothesis. The cause of arteriolosclerosis still remains to be determined.

THE STUDENTS' HEALTH SERVICE AT THE UNIVERSITY OF MINNESOTA

THE Students' Health Service of the University of Minnesota was established in 1918 because the University administration felt that it had a responsibility for the health of the students on the University campus. The policies and activities of the Health Service since its inception have been designed to attempt to prevent illness among University students and thus prevent the economic loss resulting from time lost from school.

The activities of the Health Service include complete physical examinations and health conferences for all students who enter the University; the control of communicable diseases; health examinations for all students who wish them, and as a requirement for students in the Colleges of Medicine, Dentistry and Nursing; clinical service for medical advice or care throughout the day and emergency service at night; hospital care for students in need of hospitalization; and dentistry, x-rays and laboratory service.

The health examinations required on entrance to the University, as well as the periodic examinations, are used not only to detect students who may have some communicable disease which might make them a danger to the University community but also as a basis for discussing with the student his health habits of living while at the University. Routine tuberculin tests and chest x-rays of positive reactors are a part of all complete physical examinations. Each year new cases of active tuberculosis are discovered as a result of this case-finding program. The Wassermann test is done routinely, also, as a part of the examination. Although the incidence of syphilis in the University population is very low, we believe the educational value of the Wassermann test makes it worth while. Many minor defects, such as malnutrition, dental caries, impairments of hearing and vision, et cetera, are found. Students are advised about having such defects corrected.

Medical service is available to students through the out-patient dispensary of the Students' Health Service. Students are encouraged to report to the dispensary with minor illnesses. Because of this fact not infrequently contagious diseases are discovered in the prodromal period, and thus the prevention of exposure to other students is attained. Approximately 90 per cent of the conditions for which students consult physicians in the Health Service dispensary are of such a minor nature that, were it not for the availability of the Health Service, no medical care whatever would be sought.

Any University student may be admitted to the Health Service infirmary, although the policy is to advise students who have family physicians to go home and place themselves under their care. The primary reason for providing an infirmary on the University campus is to care for students living in dormitories or rooming houses. These students who are living away from home make use of the Health Service infirmary and are hospitalized even for minor illnesses.

Ever since the Health Service was first started it has attempted to coöperate in every way possible with physicians engaged in the private practice of medicine. Occasionally we hear a report that the Health Service frequently performs surgical operations upon students who can afford to pay the fees of private surgeons. The facts are that only students who are self-supporting are given surgical care at the Health Service. As over 60 per cent of all students in the University are either wholly or partially self-supporting, a number of operations are done at the Health Service each year. Since no surgical fees are charged for these operations, the Health Service has nothing to gain by the performance of the operation, and obviously no member of the staff wishes to assume responsibility which he can pass on to someone else. The policy, therefore, has been to coöperate and not compete with the practicing physicians and surgeons in the state.

It is our hope that most of these students when they leave the University will have a much better understanding of modern medicine than they ever had before and will have learned to seek medical service promptly when ill, as well as seek the advice of the family physician for preventive medical work.

Ruth E. Boynton, M.D.,
Director.

EDITING AND PUBLISHING COMMITTEE

The resignation of Dr. James T. Christison from the Editing and Publishing Committee terminates twenty years of continuous and active service on the committee. Appointed in 1919, Dr. Christison has taken a deep interest in the journal's welfare and growth.

Dr. Christison has always taken an active part in medical organizations, for besides serving on numerous committees, he was president of the Ramsey County Medical Society in 1917, president of the Minnesota State Medical Association in 1929, and a state representative in the House of Delegates of the American Medical Association at the time of his retirement from active practice. It is the wish of the journal that Christy will be able to devote many years to his outside interests after many years of medical practice.

At its meeting in February, the Council appointed Dr. Thomas Gage Clement of Duluth to take Dr. Christison's place on the Editing and Publishing Committee. His appointment is the first to be made outside the Twin Cities and Rochester.

AMENDMENTS OF THE MINNESOTA BIRTH REGISTRATION LAW

The following announcement has been received from the office of the Minnesota Department of Health, of which A. J. Chesley, M.D., is secretary and executive officer:

Amendments of the Minnesota birth registration law enacted into law during the 1939 session of the Legislature, of interest to physicians, particularly to those practicing obstetrics and to those holding the official position of local registrar in cities, shorten the attending physician's time of reporting births to local registrars to five days, change the local registrar's time of reporting to the State Registrar to the fifth of the month, provide that physicians shall report births of illegitimate children direct to the State Registrar, and that the State Registrar may make and file replacement or substitute birth certificates under certain conditions.

Amendments Affecting Physicians

Physicians must report births to the local registrar within *five*, instead of within ten days.

Physicians must file birth certificates of illegitimate children direct with the State Registrar, not with the local registrar. The State Registrar must in turn send an abstract containing the surname of such child, the sex, and the date of birth to the local registrar, with instructions concerning its disposition, and instructions to direct anyone making inquiry about the birth record to the State Registrar.

When the attending physician is unable to certify the cause of death on the death certificate because of incomplete findings, he may substitute for the cause the statement: *"Cause not yet determined."*

Substitution of New Records

The State Registrar may make a substitute birth record whenever he receives proof satisfactory to him that:

(a) The parents of an illegitimate child have married each other.

(b) A court of competent jurisdiction has entered a judgment, order or decree relative to the parentage or adoption of a person.

When a substitute certificate is made, the original certificate and all documents pertaining to it must be withdrawn from the active file of birth records and placed in a sealed envelope in a confidential file. The envelope may be opened only upon written order of the State Registrar or of the court, and the original certificate may be copied only upon order of a court of record.

MINNESOTA LEGISLATURE PROVIDES FOR STUDY OF OCCUPATIONAL DISEASE UNDER WORKMEN'S COMPENSATION LAW

In the hope of determining what diseases are the result of occupational endeavor the 1939 Minnesota Legislature enacted a law providing for the reporting by physicians of cases believed by the medical profession to be the "result of the nature of the employment" of the particular individual. Ordinarily a workman is entitled to compensation and medical care at the expense of the employer only in the case of an accident arising out of and in the course of his employment. However, under the law as it has been for a number of years, certain diseases classified under the statute as the so-called "occupational diseases" are compensable in the same manner as accidents. The difficulty with the law, as it exists today, is that one worker with a disease listed under the law is compensated while another in perhaps the same industry with a different ailment is not compensated.

Many members of the medical profession have had the sad experience of devoting a great amount of time and effort to the treatment of an ailing workman, only to be informed that the ailment is not listed under the law as compensable, and therefore the physician cannot look to the employer for remuneration for his services. The law just enacted is quite simple in its terms, and is published in full below. When first introduced in the Legislature the bill had a penalty clause for failure of the physician to comply with its terms. It also provided that the report must be made within forty-eight hours. Both of these sections were stricken at the request of the Minnesota State Medical Association and the operation of the law placed on a purely voluntary coöperative basis. The importance of this study to the injured or ailing workman and to the medical profession cannot be over-emphasized. A prompt and enthusiastic coöperation on the part of the medical profession will enable all of us to assist in determining what amendments should be made to the present law on occupational disease. So that the physicians may have a better grasp of the problem there is also being published herewith the present Minnesota law on occupational diseases that are compensable.

Remember! the purpose of the 1939 law is to determine what diseases are of occupational origin in a given case. Read the law over carefully and then follow it. KEEP A COPY OF EVERY REPORT SENT TO THE STATE DEPARTMENT OF HEALTH. The Minnesota State Medical Association wants your suggestions and advice in this matter.

Committee on Public Policy,
Minnesota State Medical Association,
L. L. Sogge, *Chairman.*

CHAPTER 322—H. F. No. 651
A BILL

FOR AN ACT to provide for the investigation and control of poisoning and disease contracted as a result of the nature of employment, and for the reporting of such cases of poisoning and disease.

Be it enacted by the Legislature of the State of Minnesota:

Section 1. Any physician having under his professional care any person whom he believes to be suffering from poisoning from lead, phosphorus, arsenic, brass, silica dust, carbon monoxide gas, wood alcohol or mercury or their compounds, or from anthrax or from compressed-air illness or any other disease, contracted as a result of the nature of the employment of such person, shall, within five days, mail to the state department of health a report, stating the name, address and occupation of such patient, the name, address and business of his employer, the nature of the disease and such other information as may reasonably be required by said department. The department shall prepare and furnish the physicians of this state suitable blanks for the reports herein required. No report made pursuant to the provisions of this section shall be admissible as evidence of the facts therein stated in any action at law or in any action under the workmen's compensation act against any employer of such diseased person. The state department of health is authorized to investigate and to make recommendations for the elimination or prevention of occupational diseases which have been reported to it or which shall be reported to it in accordance with the provisions of this section. Said department is also authorized to study and provide advice in regard to conditions that may be suspected of causing occupational diseases, provided information obtained upon investigations made in accordance with the provisions of this section shall not be admissible as evidence in any action at law to recover damages for personal injury or in any action under the workmen's compensation act; provided further, that nothing herein contained shall be construed to interfere with or limit the powers of the department of labor and industry to make inspections of places of employment or issue orders for the protection of the health of the persons therein employed. Whenever upon investigation by the state board of health said board reaches a conclusion that a condition exists which is dangerous to the life and health of the workers in any industry or factory or other industrial institutions, it shall file a report thereon with the state department of labor and industry.

Approved April 20, 1939.
